MARCH 1975

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

- Published at George Banta Co., Inc., Menasha, Wisconsin.

- The American Economic Review, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

- Membership dues of the Association are $23.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature*. Junior membership at $11.50 per year is available to registered students for a maximum of three years. Subscriptions (libraries, institutions, or firms) are $34.50 a year, and only subscriptions to both publications will be accepted. Please write the Secretary's office, Nashville, Tennessee for single copy prices.

- Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, Rendigs Fels, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class and are not forwarded by the Post Office.

- Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

Walter W. Muller

What's Right With Economics?

By Walter W. Heller*

I come here with no eye-opening report from the frontiers of economics, no stirring cry for reform of conventional economics, no closely reasoned analysis of an economic dilemma or puzzle, no scathing or reproachful scolding of the profession for its technical preciousness or moral blindness, no report on painstaking research results, no valedictory on a lifetime of theoretical or empirical contributions. The AEA presidential addresses have been all of these things.

But tonight, going against our current fashion of telling the world what's wrong with economics, I offer a modest contribution to the immodest subject of what's right with economics—and, in particular, what's right with economics as a guide to public policy. In doing so, I won't ignore the dark side of the moon—indeed, I can't, since I will deal at some length with the bedeviling subject of inflation. But believing that it is at least as reasonable to judge a discipline by its successes as by its failures, I intend to accentuate the positive.

I. The Critical Look Inward

In recent years, as I shall illustrate in a moment, we have instead accentuated the negative. In good part, this has taken the becoming form of *mea culpa* or rather *nostra culpa*. We have, for example, readily confessed that the inflationary shocks of 1973–74 caught not just the economy but the economist by surprise. On this and other fronts, the chorus of self-criticism has risen to a new crescendo. It is almost as if we take pride in our humility. Nietzsche must have been thinking of economists when he observed that "he who despises himself nevertheless esteems himself as a self-despiser."

This is not to imply that economists' criticisms are all self-inflicted wounds. Far from it. Often among our colleagues' favorite targets are the shortcomings of mainstream economics, the misuse of modern techniques, the fallacies of conventional wisdom—in each case, the target is not the critic's but his colleagues' brand of economics, not *mea culpa* but *eorum culpa*.

In any event, he who comes to praise economics risks being buried in the barrage of indictments that economists have brought against themselves and their brethren. Let me give you a sampling of some that will be ringing in my ears as I follow the parlous path of economic virtue.

Ceremonial occasions—presidential, memorial, or inaugural addresses—in particular seem to evoke musings on the troubled or even dismal state of our science. For the AEA faithful, I need only recall John Kenneth Galbraith condemning neoclassical and neo-Keynesian economics for ignoring power and thus losing contact with the real world; Wassily Leontief attacking mathematical economics for building a showy superstructure on weak empirical foundations and unverified assumptions, and thus losing contact with the real world; Kenneth

---

* Presidential address delivered at the eighty-seventh meeting of the American Economic Association, San Francisco, California, December 29, 1974. The address was abridged for oral delivery. I owe particular thanks for the many conversations I held with Francis Boddy, Otto Eckstein, Edward Foster, Arthur Okun, Joseph Pechman, George Perry, Robert Solow, and James Tobin. I also wish to thank Gardner Ackley, Kenneth Arrow, Walter P. Heller, John R. Meyer, Franco Modigliani, Alice Rivlin, Paul Samuelson, Charles Schultze, Christopher Sims, and George Stigler, for contributions to the adult education that underlies this address. The errors of course are mine.

Boulding assailing welfare economics for its reliance on that holiest of holies, Pareto optimality—when in fact "our lives are dominated by precisely this inter-dependence of utility functions which the Paretian optimum denies"—thus also losing contact with the real world.

In one form or another, variations on Leontief's lament have been heard in many another presidential address, to wit:

> By F. H. Hahn (Econometric Society, 1968), who decried "the spectacle of so many people refining the analysis of economic states which they give no reason to suppose will ever, or have ever, come about. . . ."

> By G. D. N. Worswick (Section F of the British Association, 1971), who viewed the performance of economics as "curiously disappointing," suggesting that it has "a marvelous array of pretend tools which would perform wonders if ever a set of facts should turn up in the right form."

> By E. H. Phelps Brown (Royal Economics Society, 1971), who judged the usefulness of current work in economics as "not equal to its distinction" because it is "built upon assumptions about human behavior that are plucked from the air."

> By James H. Blackman (Southern Economic Association, 1971), who noted that models with sufficiently intriguing mathematical properties can achieve lives of their own even if they lead the investigator further away from reality and yet, "the profession's incentive system tends perversely to reward this kind of endeavor and to deflect the attention of gifted economists from the exploration of concrete problems and the dirty work that entails."

> By Sherman Maisel (American Finance Association, 1973), who concluded that most of the literature of monetary economics is "non-operational" since its prescriptions are too often based on limited or false assumptions, it by-passes critical operational problems, and it ascribes too great validity to its statistical tests.

> By Barbara Bergmann (Eastern Economic Association, 1974), who prefaced her plea for more microsimulation to incorporate "realistically messy information" in our economic data base with a few roundhouse swings at the economics profession and the pointed observation that instead of studying the real nature of decision making, we typically rush to make assumptions "whose purpose in life is to let the theorem emerge, all neat and provable."

Another favorite line of criticism and attack focusses on the implicit value premises of conventional economics. Gunnar Myrdal and Robert Heilbroner chide us for concealing the value judgments that inevitably enter into our selection of problems for study, choice of approach, definition of concepts, and even gathering of data. So a "value-free" economics is an illusion—they urge economists to specify their values and thus avoid biases and make research more realistic.

Radical economists simply reject the whole value system of conventional economics—as they see it, the neoclassical paradigm in its very bone and marrow enthrones acquisitiveness and enshrines the existing order. Paul Sweezy accuses mainstream economists "of hiding the facts, of making the uncontrollable appear under control, of rationalizing a system which condemns hundreds of millions of people to lives of despair and starvation. . . ."

Inflation is the latest source of critical volleys, and I will get to these in due course. Meanwhile, the sampler of economic masochism I have already provided should serve as ample insurance against complacency or smugness in considering "what's right with economics." At the same time, it strongly suggests that economics, more than any other social science, is afflicted with the common scold.

I recognize that such a quick sampling and cryptic quotes, selected to highlight criticism, do a certain injustice to economics and to some of the quoted economists whose kindlier observations have been neglected in the process. But I am also aware that my litany omitted a number of familiar flaws, for example, our impounding of tastes and preferences in *ceteris paribus*; the shortcomings of the maximization principle in explaining consumer and producer behavior, especially in the short run; and our limited ability to bring the claims of future generations into our social utility functions.

Were I to serve as defense counsel for the profession on this wide variety of indictments, I would urge that we plead guilty or take the Fifth on some, take to the defense on others, and take offense at the rest. Having paid my respects to the critics, I intend no point-by-point evaluation or rebuttal. This has been ably undertaken by others.[1] Rather, my object is to gain a more balanced perspective by focussing on the quality, role, and contributions of economics, especially to public policy. In that undertaking, the first step is to examine the flank we expose to the public.

II. The Economist and the Public

When we turn from inside to outside critics, the focus changes. We may think, rightly, that freely confessing our weaknesses and airing our differences stimulate responses and adaptations that strengthen economics. Yet, wearing our purple hearts on our sleeves has its price. It nourishes the darkest suspicions about our art and supplies live ammunition to outside critics who have declared open season on economists. Witness the open sesame to the ed-op pages for such recent thrusts as Bergmann's assault on economists in general and Friedrich von Hayek's attack on Keynesians in particular. With everything from off-the-cuff phrases about being "caught with our parameters down" to tracts for the *Times*, we feed the hand that bites us.

This is not a plea to do our self-flagellating in secret or to mute our disputes and conflicts. Open controversies, openly arrived at, are part of the therapy that keeps our profession healthy. Rather, my plea is to the media and the opinion makers to understand that appearances are deceiving, that hard give-and-take is indeed a symbol of strength, and that our areas of agreement and consensus are vastly larger than our areas of difference.

On the first point, observers from other disciplines are often astonished at how hard economists go at each other, how readily they run the gauntlet of their colleagues' criticisms with no quarter asked and none given—and, with few exceptions, all this within the framework of professional respect and friendship. As Charles Frankel put it, unlike other social sciences, economics seems to have achieved "a working etiquette which allows people to disagree vigorously without engaging in recrimination about 'unscientific' or 'unprofessional' behavior" (quoted in Johnson (1973)).

What accounts for this? Part of it, one can unblushingly say, is simply that so many competent, tough, and rigorously trained minds have been drawn into economics in response not just to challenging policy problems but to the quantitative revolution since World War II. And part of it is that the participants can draw on a hard core of economic theory and methodology, together with a growing body of empirical knowledge, to provide standards for testing the validity (though not necessarily the relevance and reality) of ideas, analysis, and empirical findings. The result is not only a relentless intellectual policing of the profession that soon exposes the fool, the quack, and the charlatan, but a growing capacity "to participate in adversary debate over public policy issues without jeopardizing scientific integrity and freedom" (Johnson (1973)).

---

[1] Among those who have sprung to the defense with varying degrees of fervor are Harry Johnson (1968), Donald MacDougall, Charles Schultze (1972), Robert Solow (1970, 1971), and James Tobin (1973, 1974). For more general appraisals of the criticisms and the state of economics, see Blackman and Nancy Ruggles.

That brings me to the second point, the impression we give outsiders of a house divided, not to say splintered. It is worth reminding ourselves and our critics of several factors that drive a wedge between image and reality.

One, instead of laying aside our differences and living contentedly together, we economists tend to lay aside our agreements and live contentiously together. We focus our private and public debates on unsolved policy problems, tough analytical nuts, and issues on which we have rival theories, contradictory evidence, or strong ideological differences. Just as these are the questions that intrigue us, they are the ones that attract the attention of press and public. What we know—and they may not—is that beneath the visible tip of disagreement and rivalry lies no huge iceberg of divisiveness.

Two, it is only occasionally that our areas of consensus are brought to the surface in a newsworthy way. One such occasion was the White House "summit conference" on inflation last September. Two dozen leading economists from across a wide spectrum of American economics (not wide enough, the radicals would say) signed a statement which called on the President and Congress to eliminate twenty-two restrictive laws and practices that inhibit competition, inflate costs, and prop up prices. Only a tiny minority held out (if any minority that includes Galbraith can be called "tiny"). Even more striking, in a sense, was that while the customary and largely ideological clashes among, say, Galbraith, Milton Friedman, and Paul Samuelson caught the public eye, the real story lay in the minimal dissent among the participants on (a) the forecast of a soggy or sagging economy, (b) the urgency of providing relief to the victims of inflation and the casualties of recession, (c) the need to ease monetary restraint, (d) the small anti-inflationary payoff on moderate ($5 to $10 billion) budget cuts, and (e) the advisability of resisting popular demands for reimposing full-scale wage and price controls.

Three, even where disagreement flourishes—most visibly, perhaps, between Keynesians and monetarists—the public may not discern that the analytical and empirical ties that bind us are far stronger than the forces that divide us. Our controversies take place within the context of basic consensus on the nature and methods of economic theory and inquiry, on the content of the disagreement, and on the kinds of tests that may one day resolve the conflict. "Such disagreement within agreement lies at the heart of the process of normal development of a science" (Benjamin Ward, p. 12).

Four, much of what the public perceives as a clash of economic concepts and findings is in fact a clash of ideology and values. Given the way technical economics and ethical preferences are packaged in policy debates (and given our lapses in identifying which is which), this is hardly surprising. Thus, whoever opens the package labeled "monetarist" typically finds not just money supply in full flower, but a dedication to minimum government intervention, small budgets, reliance on rules rather than authority, and price stability. Contrasting correlations appear in the Keynesian package. So outsiders can be excused for slipping into the fallacy of association and attributing the split to our unresolved analytical conflicts rather than to divergent evaluations of social priorities and competing philosophies of government. These associational chains are not linked together by any inexorable logic—in part, they seem to be an accident of birth as in the case of the Chicago twins of monetarism and *laissez-faire* rules. A belief in the supremacy of monetary over fiscal tools could quite logically go hand-in-hand with avid interventionism. But this escapes the jaundiced eye of the outside observer, who takes the ideological lineup as further evidence that economics is riven to its core.

Five, there is an ironic but substantial inverse correlation between the degree of consensus among economists and the degree of public acceptance of their findings. Thus, in the macro-economic sphere of stabilization policy, where debate and disputes among economists flourish, their imprint on public policy is undeniable. But in the considerably more peaceful realm of microeconomics and allocative efficiency —where a reliable analytical apparatus coupled with solid quantitative work, especially on costs and benefits, has led the great majority of disinterested economists to an agreed diagnosis and prescription— the policy box score shows few hits, fewer runs, and lots of runners left on base. Economists widely, in some cases almost uniformly, favor tougher antitrust policy, freer trade, deregulation of transportation, pollution taxes in place of most prohibitions, and tax reform to remove income tax shelters. They oppose fair trade laws, restrictive labor and management practices, distortive zoning laws and building codes, import quotas, ceilings on interest rates, maritime subsidies, and pure (or impure) pork barrel projects.

Granted, the diffuse and inchoate consumer interest has been no match for the sharply focussed, articulate, and well-financed efforts of producer groups. But the economist is beginning to pick up some allies. Public interest groups are increasingly giving focus and force to the consumer and general public interest. And the march of events is providing some windfalls: Among the apples that have dropped in our laps are flexible exchange rates, the dethroning of agricultural price supports, inroads on import quotas, and moves to end percentage depletion. Under the pressure of virulent inflation, government actions that erode productivity and boost costs and prices are being subjected to new and searching scrutiny. So perhaps, on these micro-economic issues where economists sing in reasonably close harmony, the outside world will no longer quite tune us out. In macro-economic policy, where cacaphony prevails, we can be sure that the world will tune us in.

It may also be useful to draw attention —especially the attention of those who interpret us to the public—to certain other misperceptions and roadblocks that thwart good economics and tend to put economists in bad repute.

First, much of our economic analysis and the uncommon sense growing out of it fly in the face of "common sense," for example: that budget deficits need not spell inflation, nor national debt a burden on our grandchildren; that thriftiness can be a mixed virtue; that while exploding oil prices *in*flate costs, they *de*flate demand; that in an overheated economy, greater taxes can be the lesser evil; and so on. Behind every false dictate of common sense lies a primitive and misbegotten economic theory—and for most of our pains to correct it, we can expect to get the back of everyman's hand.

Second, a related cross to bear can be characterized by Kermit Gordon's apt phrase, "virtue is so much easier when duty and self-interest coincide." Not only does that foredoom action on many microeconomic fronts, as already noted, but it puts roadblocks in the path of efforts to make fiscal policy a two-way street. For forty years, Congress has enacted major tax increases only under the whiplash of war. The resulting reliance on tight money to fight peacetime excess demand, coupled with expansionary fiscal policy to fight recession and slack, have had an unmistakeable ratchet effect that has tilted the system toward tighter money and easier budgets. (Small wonder, by the way, that many economists and policy makers are unwilling to give up, via indexing, the increases in effective income tax rates "legislated" by inflation.)

Third, the public sees economists as the bearers of hard and unpalatable truths. And often we are, by the very nature of our sometimes dismal discipline. Except when idle resources can be put to work or productivity increased, our message is the stern one of tradeoffs, benefits at a cost, and no one-dimensional daydreaming. Even worse, at times economics has to bring the bad tidings that for some problems there are no satisfactory solutions. For some thirty years, we have warned that full employment, price stability, and full freedom of economic choice cannot coexist in a world of strongly organized producer groups. More recently, economic analysis has brought home the unromantic truth that failure to cure some of our social ills traces less to a failure of will, or "right-wing villains," or a calloused "establishment," or powerlessness of the people, than it does to the prosaic facts that the problems are tough and complex and the goals we seek may be irreconcilable—in short, trace more to conflicts in our national objectives than to conflicts among social groups. Welfare reform is a case in point: no solution can simultaneously provide a decent minimum income for all, preserve work incentives, cut no one's benefits, and avoid huge budget costs (see Schultze (1972); Rivlin (1973)). *We* may view such work as a contribution to straight thinking and rational choice. Our critics are more likely to view it, at worst, as a counsel of defeat (which it is not) or at best a counsel of inescapable compromise (which it is).

Since the foregoing misperceptions and roadblocks thwart the translation of good economics into good policy, one could justify, in cold cost-benefit terms, a sizeable investment to overcome or reduce them. The most obvious implication is that the country needs to invest more in formal economic education at all levels. But an equally pressing need is for economists to invest more of their time and effort in making themselves understood to the public and policy maker—and that in turn requires recognition of this skill in the academic reward system. This might serve as a useful antidote to the influence of mathematics and econometrics which, while heightening the precision of professional thinking and internal communication, have apparently dulled the appetite and eroded the facility to communicate with the public in intelligible English prose.

In a very real sense, this confronts the press with an unusual opportunity and challenge, perhaps even a responsibility, to serve as a translator and interpreter of economics and its offerings. But believing (probably rightly) that their readers and listeners prefer to hear of fights and failures, crises and controversies, rather than of quiet contributions and consensus, the conventional or electronic press is not very likely to rise to this challenge. So it is still up to economists. But I must not carry this too far. Just as I am eschewing any Cassandra-like pronouncements tonight, so I have promised myself to suppress the oracular and even the avuncular (Dutch-type) mood evoked by these occasions. So I shall press on.

III. Standards of Judgment

From the foregoing, it is evident that I feel, first, that economists have gone beyond beguiling humility and welcome self-criticism to the point of almost neurotic self-rebuke, and second, that press and public have all too lustily taken up the cry—in part taking us at our word, in part misinterpreting us, and in part reflecting their belief that, after the high promise of the 1960's, we have failed them in not foreseeing and forestalling the crises of the 1970's: stagflation, energy shortage, and the environment.

In my quest for a more balanced perspective on the state of economics, the next task is to set up some standards for judging the quality and performance of economists. Since we have developed no measures of output or allocative efficiency, no capital-output or cost-benefit ratios, for the economics "industry," I will have to fall back on more subjective and less quantitative measures in judging its quality and contributions.

My mixed bag of criteria includes (1) the quality of inputs; (2) the demands for our services; (3) as a proxy for a measure of outputs, the record of accomplishment in a given field (public finance); (4) finally, the cruelest test, our handling of the economics of inflation.

The *potential* of economics for informing and improving public policy depends on the stock of human capital, technology and tools at its command. Here, economics has no difficulty in holding its head high, especially in terms of the striking advances of the past three or four decades.

Harry Johnson may be a trifle extravagant in his assessment that the United States now has "perhaps fifty economic departments of an average quality comparable to the average quality of the four or five best departments in the whole world in the pre-World War II period . . ." (1973), but only a trifle. Another attest to professional quality, already referred to, might be put this way: Show me another field that has enough inner strength to confess so much remaining weakness (and to carry on so much open controversy). Humility where we have things to be humble about (and we do) is a becoming trait. But coupling it with pride where we have things to be genuinely proud about is hardly a deadly sin.

Accompanying the growth in the quantity and quality of economic brainpower have been striking advances in the techniques and tools with which economists work. For this audience, I can speak in shorthand about the strengthened analytical base of micro- and macroeconomics; the methodological revolution that moved us from the rationalist-historical approach into the age of quantification, with its insistence on systematic measurement of the shapes of economic functions and empirical testing of hypotheses and its use of econometrics and simulation techniques (with a powerful assist from the computer); and such conceptual advances as those in the economics of human capital, of cost-benefit relations, of uncertainty, of control, of transactions and information costs, of "second best," and of the allocation of time.

In normative economics and the analysis of value-laden social problems, new frontiers in the study of economic behavior are being opened up by survey research techniques (especially by the Michigan Survey Research Center), by efforts to measure nonmarket benefits or values (especially by the National Bureau of Economic Research) and by "controlled" social experimentation (for example, by the Brookings Institution and the University of Wisconsin Institute for Research on Poverty). These newer tools and the institutions that nurture them constitute part of the rich and expanding resources of economics.

Economics can also draw on a broad data base, especially in federal statistics. But here, the quantity, timeliness, and even the quality of the data are not keeping pace with either the problems requiring analysis or the capacity of our quantitative techniques. Responding to policy needs and mounting self-criticism, the profession has opened many new fronts in the search for realistic micro-data to link up with macro-data, for cross-section data to help overcome the curse of collinearity in time-series analysis, and for custom-built data developed by survey and experimental techniques.

That the human, analytical, and quantitative resources of economics provide a huge potential for solving problems seems undeniable. That more of these powerful resources than ever before are being put at the disposal of economic policy makers also seems undeniable. What we do not know is what proportion is being misdirected into arid puzzles, sterile proofs, and recreational mathematics while the world's pressing economic and social problems go begging for answers. Here, we can only match one observer's impression against another's. The profession itself has not come to grips with *this* question of allocative efficiency.

A second test in appraising the state of economics, one not unknown to economics, is that of the market place. This takes several forms, none very robust, but none trivial. The first is the upsurge in enrollments in economics courses, especially in introductory economics, that has occurred in the academic years 1973–74 and 1974–75. The second is the oft-reported high ranking of economists' salaries in business, government, and academic life. A third is the strong and growing demand for economists' inputs into the policy-making process—either as staff members or as expert witnesses for congressional committees, individual congressmen, and the executive branch.

With students, business, and government beating a path to our door, we can infer that something must be right with economics, or wrong with the economy, or both. Either we are building a better mousetrap or there are more and bigger mice threatening our customers. Perhaps it is simply that we have the only mousetraps in town.

But there must be more to it than that. Take the policy maker, for example. What he finds congenial is that he can hand an economist a problem—relating to changes in taxation, regulations, budget proposals, pollution control, poverty, social security, public service jobs, gasoline taxes, oil prices, and so on—and be reasonably sure of getting a useful appraisal of alternative paths to his objectives, of costs and benefits, and of distributional, allocative, and stabilization impacts. Many of these judgments will come with orders of magnitude or reasonably precise numbers attached. He may not trust our *GNP* forecasts, but he has come to respect our hardheaded analysis and numbers on the myriad problems of economic choice with which he is faced.

It seems fair to draw another inference: notwithstanding the current wave of self-criticism and public criticism, even lampooning, of economists and despite our highly visible public debates and highly vulnerable participation in policy making, economics continues to maintain its standing as a science. Signs of a reported crisis of public confidence or of a "recession of self-confidence" are few and far between.

Reports of the demise of our discipline are grossly exaggerated.

IV. The "Outputs" of Public Economics

Having considered some indicators of the quality of our inputs and of the revealed preferences for our outputs, let me continue this exercise in casual (and congenial) empiricism by taking an unscientific but not unrepresentative sample of the outputs of economics, especially those bearing on policy. For this purpose, I draw on my chosen field of public finance, or public economics, to illustrate the telling conceptual and empirical advances of economics in recent decades and the resulting enrichment of its offerings to the policy maker. Indeed, such an appraisal offers so many healthy antidotes to "what's wrong with economics" that I was tempted to devote my whole discourse to it tonight. But I resisted the temptation because, first, much of it has already been done in carefully documented depth in survey volumes by Brookings and the National Bureau;[2] second, I figured it might test your patience and mine; and third, it would have left no room for a confrontation with inflation. So I offer instead a miniaturized assessment of the achievements of public economics as viewed through the policy prism.

Public Expenditures

Consider first the striking contributions economics has made in the past generation to clear thinking and better informed decisions on public expenditures. Partly, this reflects advances in economic science, for example, in the theory of public goods and human capital, and partly, creative new applications of the economist's characteristic way of looking at problems of choice, namely, through the lens of opportunity costs, benefits, and alternative paths to a stated goal.

Economics can offer much more concrete guidance on efficient ways of allocating resources to achieve stated governmental objectives than it can on what the public-private sector division of resources should be. That may be a good thing in that presidents and congressmen view the fixing of goals for public health, housing, welfare, and the like as what *they* were elected for, yet at the same time seek, or at least accept, economic guidance on the choice among competing methods of achieving these goals.

Nonetheless, rapid progress in the theory of public goods since the appearance of the Samuelson classic on "The Pure Theory of Public Expenditures" just twenty years ago has vastly improved on the simplistic theory it replaced. It has facilitated straight thinking on the derivation of conditions for efficient public-sector allocations from private evaluations and on the articulation of social priorities through the political process.

Interwoven with the newer thinking about public goods has been a resurgent interest in externalities or spillover effects. In a sense, the pure collective good is a case of total externality—all of its benefits are external and nonmarketable since nobody can be excluded from them. That may clarify thinking but gives little policy guidance.

Yet, the externality concept translates into hard-headed policy advice in such disparate areas as pollution, federal aid, and the law. When pollution became a national concern, economists quickly drew on their tool kit to develop proposals for antipollution taxes (within the context of target air and water quality standards). Tax penalties of so much per unit would put price tags on use of the public's air and water, thus internalizing external costs and using market incentives to accomplish depollution rather than relying on the less efficient route of regulation.

---

[2] See Alan Blinder and Robert Solow et al. This is the capstone volume of the Brookings Studies on Government Finance, directed by Joseph A. Pechman, which has produced 35 books in the past decade. See also Carl Shoup et al. This was one of several survey volumes under the general heading, *Economic Research: Retrospect and Prospect*, based on the Bureau's Fiftieth Anniversary Colloquia.

When local governments supply education and public health services to a mobile population, many of the benefits spill over to other units. An important rationale for federal grants flows from these externalities, namely, that to get local units to produce enough education and health service to achieve a national, not just a local, cost-benefit optimum requires conditional grants from the federal purse.

Further, since externalities in the form of damage to third parties lies at the heart of many problems in legal justice, economics is able to make an important contribution in this area.

When we turn to the empirical outputs that are now illuminating problems of public choice, we find the past decade bristling with new thinking, new techniques, and new measurements. These offer the decision maker important new guides in the selection and evaluation of government programs and new insights into alternative systems of delivering government services:

> Measurement of cost-benefit ratios has developed from the early metrics of water projects into, first, a sophisticated cost-benefit calculus for tangible investments like dams, roads, pollution-control projects and, second, cost-benefit estimates for intangible investments in human brainpower, skills, and health. Shadow pricing has been one of the useful tools in this connection. Cost-benefit analysis, even with its limits of quantification and its inability to shed light on distributional and value questions, is an important aid to informed decisions.
>
> A related advance is the development of new and tougher standards for judging government programs. The former criteria centered on the question: Is the program put into effect quickly and with high fidelity to the congressional intent? Now, the accountability question is: Does it deliver the goods? Does it accomplish the objectives? Inputs used to be stressed—if they conformed with the intent of the legislation, they tended to be judged a success. But now we try to measure outputs, a tougher and more elusive standard. (The parallel with judging the performance of economics and economists is painfully obvious.) Antipoverty programs, which were among the first to be evaluated by these stringent standards, seem to have borne the brunt of the evaluation boom. By the old inputs standard, a program like Head Start would have fared much better.
>
> The reach of cost-benefit analysis will be lengthened if a broad range of new research efforts in nonmarket sectors of economic activity pays off. I refer not only to the exciting work on measurement of the returns on investments in human capital (T. W. Schultz), but to efforts to measure the output of the medical industry, to measure the relations between crime and punishment, and to measure the value of nonmarket economic activity conducted *within* firms and households.
>
> The new technique of controlled social experimentation on proposed welfare and housing measures, health insurance, and education vouchers is yielding important insights. As a result of experiments on negative income taxation, for example, the equity versus efficiency, or equality versus incentives, controversy will never be conducted in a vacuum

again (Rivlin (1973)). In spite of some limitations, the New Jersey experiment yielded strong evidence that fears of fatal incentive effects of a negative income tax were grossly overblown.

Another focus of fruitful thinking relates to alternative strategies for delivering social services. The in-cash versus in-kind choice is a basic one. Economists are predisposed toward the in-cash approach on grounds that one can generally depend on people to follow their own best interests. But there are significant exceptions where consumer sovereignty is limited or specific goods externalities exist or some explicit social values take priority.

Out of economics also comes the attempt to develop "market analogs" to serve as substitutes for market incentives in reconciling public with private interests, decentralized individual decisions with social goals. Pollution taxes are a case in point. Performance standards for teacher pay would be another. Putting medical insurance programs on an efficiency-based reimbursement basis would be a third. The big gap is in the redesign of incentives and institutions to guide decentralized government decision making more systematically toward the aims of our social programs (Schultze (1971)). Thus far, the government, like the economics profession, is largely in the dark about its own production function.

Taxation

What strikes an old public finance functionary as forcibly as any change in the field of public finance is the way in which modern thinking has knocked the props out from under the neat and primitive theories of tax incidence of a generation ago. The property tax provides a particularly instructive case in point. The textbooks of the 1930's and 1940's told us confidently that the tax on land (fixed supply) was capitalized and on dwellings (supply-responsive) fell like an excise tax on the occupant, the consumer of housing services. The policy lesson was clear: Given the declining proportion of income spent on housing services as income rises, the tax was hopelessly regressive. Today? It is recognized that the old incidence analysis was wrong, even on its own terms.

The modern theory of incidence (defined as the impact on distribution of private real income) draws on general equilibrium theory, distinguishes between sources-of-income and uses-of-income effects, and disentangles the concepts of specific, differential, and balanced-budget incidence. The resulting analysis indicates that much of the aggregate burden of the property tax falls on owners of capital and hence tends to be progressive—and this progressivity is enhanced by the particular "excise-type" effects of this tax (Henry Aaron). In short, error has been exposed and though the debate is not over, we are now in transit toward truth.[3] It is hard to put down the knee-jerk reaction that prefixes "property tax" with "regressive." And it will take some time before policy makers accept the proposition that, at the very least, the property tax is now in the unexpected position of "innocent until proved guilty." But the implications for policy are profound.

Economists have long been useful and influential contributors to the design of the federal tax structure and of particular taxes. Again, elementary concepts we now take for granted—for example, horizontal versus vertical equity, Richard Musgrave's three branches of distribution, allocation, and stabilization, the lagged effect of tax changes, and automatic versus discretionary tax changes were not even part of our vocabulary in the pre-World War II period. Yet, all of these are now factored into our economic advice on taxation.

---

[3] Those who view decisions to locate in a particular community as a conscious choice of one particular bundle of public services over others conclude that the property tax on housing is a benefit tax, a payment for benefits received.

Even more directly impinging on policy are the empirical advances. One thinks of searching studies of particular taxes and tax components (especially in the Brookings Studies on Government Finance), and of the relentless identifying and quantifying of federal income tax preferences or "loopholes." Much of the thrust of economists' recent work on these "tax expenditures" has been (a) to identify the beneficiaries and specify the size of the government subsidies provided in the form of preferential tax treatment, (b) to define the inequities, both horizontal and vertical, that they create, and (c) to estimate the distortions in resource flows caused by preferential treatment of oil and gas, housing, real estate partnerships, and the like, and measure the resulting welfare loss. Though the congressional response has been slow and halting, progress has been made along the lines plotted by economists, and a solid base has been laid for the further tax reform that is surely coming.

Out of the countless other advances, one stands out, namely, the highly informative work done on the distributional impacts of taxation with the aid of the powerful tool of micro-unit data files (for example, the MERGE file developed by Joseph Pechman and Benjamin Okner). Such micro-unit files are a new-generation statistical missile, MIRVed so that they can simultaneously hit multiple revenue-estimating and burden-distribution targets. With their help, for example, economists have measured the growing burden of income, payroll, and consumption taxes on the lower income groups and developed techniques for removing them—most recently, in the context of the impact of inflation on the same groups.

One should add that if revolution rather than reform becomes the order of the day in the federal tax structure, the economist is ever ready with reasonably sophisticated analytics and a fair amount of empirical information on such major alternatives as a value-added tax, a progressive expenditure tax, and a net-worth tax. One of the next stages in tax research, a highly complex one, will be the general equilibrium analysis of such sweeping changes in the tax system as, say, the substitution of a value-added tax for the corporate income tax or for part of the payroll tax. Or, if stimulation of private saving becomes a compelling objective, perhaps the substitution of an expenditure tax for part of the income tax will become a live issue. The skills of the economist will be front and center in any such redesign of the tax system.

The negative income tax story is relevant here. The concept and its rudimentary principles were developed and discussed among economists in the early 1940's. Some of us were already using it as a teaching device in the mid-1940's. A quarter-century after its origin, it became the basis for the Family Assistance Plan developed by Mr. Nixon's economists. And a more limited version of the plan seems again to be rustling in the leaves.

Fiscal Policy

In the domain of fiscal policy, it is harder to answer the question, "What have you economists done for us lately?" with a sparkling array of examples. Much of the theoretical ferment in this field is associated with the flowering of Keynesian macroeconomics in the late 1930's and 1940's, the very period when the microeconomics of tax incidence and public expenditures languished.

Conceptual advances have continued throughout the past twenty-five years, but they have been more in the nature of a fleshing out and consolidation of the original breakthroughs with the aid of the powerful tools of mathematics and econometrics. Multiplier analysis, for example, has moved from the theoretical realm into large computer models of the economy—with the tax cut of 1964 and the surtax of 1968 providing empirical grist for the mill. While the models differ on the exact value of the multiplier, "a fiscal policy planner will not often be led astray if he uses a multiplier of 2" for government spending (see Blinder and Solow).

Coupled with multiplier studies is the even more subtle study of the structure of the "outside lags," of the timing of responses in the economy to changes in fiscal policy. Though the empirical efforts and debates go on apace, the behavior of the cumulative multipliers in a clutch of economic models suggests that for any given change in fiscal policy, "at least 75 percent, probably much more, of the ultimate effect is felt within the first year after the initiation of the policy" (Blinder and Solow). Although intractable questions remain concerning investment responses to fiscal policy changes, enough has been learned about aggregate demand responses to provide two broad generalizations about fiscal policy:

> One, the conditions for intelligent fiscal policy are met if economic forecasting can answer two not-very-exacting questions: Do projected economic conditions in the ensuing six to nine months call for restraint or stimulus? Is the required dosage large or small?
>
> Two, given the limited margin for error in a high-employment economy, it is better to rely on many smaller monetary-fiscal moves than a few large ones.

Implicit in these two generalizations is a third one: Given both the internal shifts and the external shocks with which stabilization policy has to cope, a discretionary policy that makes efficient use of feedback information will be more effective than an automatic policy that locks in on fixed fiscal and monetary targets.

Development of a simplified measure of fiscal impact revolving around the "full employment surplus" (*FES*) concept is another example of the typical process by which economists expose error, develop approximations of truth, but continue the vigorous debate on further improvements. First, policy makers had to be weaned away from the annually balanced budget and the cyclically balanced budget as policy targets and from actual deficits or surpluses (especially in budgets other than the national income accounts budget) as measures of budget stimulus or restriction. It was not easy. It took almost a quarter of a century before a Democratic president was converted (in 1961) and another decade to capture a Republican White House.

But success on the policy frontier has its own pitfalls, both political and economic. What was intended as a measure of policy was instead taken as a goal, namely, a balanced budget at full employment, a "self-fulfilling prophecy" as the Nixon Administration called it. This erroneously implied that the fiscal target should remain fixed regardless of changes in monetary policy and significant shifts in private demand, for example, a plant-and-equipment boom. Apart from trying to correct such misconceptions, economists have had to wrestle with the problem of the overstatement of the full employment surplus when inflation expands revenues faster than expenditures, not to mention the problem of weighting for differing multipliers if tax or expenditure components change sharply. In brief, the advances over the bad old days of the annually balanced budget are enormous, but economists are aware of the limitations of the *FES* measure and are struggling to resolve them.

Just as economics relegated erroneous budget concepts to the dustbin, so it has cast a shadow over such former favorites (of mine, among others) as federal capital budgeting and the "shelf of public works." The initial enthusiasm for the capital budget concept (in the context of a Congress seeking to balance the budget annually) was dispelled by second-thought analysis showing that (a) it rested on some faulty parallels with private finance, (b) the implicit fiscal policy rule of always financing capital projects by borrowing is in error, and (c) it would bias government capital spending toward bricks and mortar instead of brainpower and people. In the public works case, the concept ran afoul the findings of prosaic economic research: recent studies show that the public works program launched in 1963 to speed recovery was far from completed before excess demand overtook us in the 1966–69 period. This is not to rule out the use of certain types of "public works" that are nimble on their feet, such as road and forest maintenance work, for stabilization purposes. Nor does it rule out speeding up or delaying the launching of projects that are to be undertaken for sound cost-benefit reasons in any event. But it is fair warning not to expect very much stabilization help from the public works sector (not to be confused with public service employment).

In the conscious use of taxes for stabilization purposes, the huge 1964 income tax cut delivered economic expansion and a balanced budget on schedule without inflation by mid-1965, just before the Vietnam escalation struck the economy. The temporary 1968 surtax, buffeted by powerful demand forces and monetary easing, left a more ambiguous econometric trail. Subsequent fiscal policy thinking emphasizes the advantages of temporary tax changes that embody not just income effects but intertemporal substitution effects. For example, lowering the prices of investment goods in a recession via a clearly temporary increase in the investment credit, or temporary cuts in consumption taxes on durable goods (or lacking these, temporary purchase subsidies), would constitute a powerful incentive to purchase those goods before the price went up again.

Further work is needed to measure the cost-push effects of anti-inflationary tax increases that offset part of their demand-damping effect. In recession, the cost-easing and demand-push effects work in happy harmony. They work at cross purposes in tax increases (though not in expenditure cuts) to curb inflation. The question of how large the offsetting cost-push effects, or aggregate supply effects, may be, is unresolved. In a high-inflation economy, this is a serious gap in our fiscal policy knowledge.

Other Aspects

This kaleidoscope of contributions, long as it is, leaves out a whole string of developments in budget concepts, techniques, and processes—efforts that were crowned by the congressional budget reforms recently put into effect. Much of the guidance and momentum for these reforms was provided by economic analysis and by a succession of five economist-budget directors throughout the 1960's. Also omitted is the conceptual work on the economics of the bureaucratic process, of how government works. Other omissions include the rebirth of interest and great advances in the economics of state-local finance, the rapid growth of the important new field of urban economics—with its contributions to regional economics, location research, and analysis of the city as an economic system—and the enriched economics of fiscal federalism. I have even eschewed an assessment of revenue sharing, the rationale and form of which were developed by economists. With little imperialism, economists can also cite the firm quantitative evidence being developed to demonstrate the adverse economic effects of many public regulatory activities.[4]

For all the advances, the agenda of unresolved conceptual questions and unfinished empirical business is huge. But even this truncated review of progress and current output in public economics makes clear that the contributions of recent decades have enormously enriched this field not only conceptually but as a source of hard practical advice to decision makers who want to shape a better tax system, do justice to the poor, improve social programs, reform budget procedures, fight unemployment, and so on. And in the process, the frontiers of normative economics, both theoretical and empirical, have been pushed out into the areas of education, health, racism, crime, family behavior, and even political behavior.

As a result, we have plunged ever deeper into the realm of values. Not that it was a value-free inquiry to ask the traditional questions about the effect of a given policy on material output. But surely the testing of policies by the costs they incur and how effective they are in meeting some generally accepted criteria of social welfare or general welfare involves economics directly in value and distributional problems. And it enables economics to say important things on social policy issues within the framework of the conventional economic paradigm and with rigor of the non-mortis variety.

We are becoming interdisciplinary in spite of ourselves. When *we* do it, of course, we don't think of it as cross-sterilization of disciplines. But here is an area where modesty becomes us. For if we confine ourselves too narrowly to economics, we are far too likely to attribute to economic variables the behavior and results that are really a response to social variables. Fearing just that, one observer has been unkind enough to suggest that we ought to stick to inflation problems where we *all* know what to say.

V. The Economist and Inflation

Inflation may no longer be "Public Enemy Number One" now that severe recession is upon us, but it is surely "Economists' Enemy Number One." Among the charges of, by, and against economists that have been touched off by double-digit inflation and reported in the public prints are these:

> Economists have confessed (I plead guilty) that 1973 was "the year of infamy in inflation forecasting" and, as already noted, that "we were caught with our parameters down."
>
> Aaron Gordon puts it more explicitly when he says that "the forecasters fell flat on their faces in predicting price changes because they didn't have any way of estimating sectoral supply scarcity" and adds that we have not "even started to develop a theory of aggregate supply."
>
> Leontief scolds macroeconomists more generally: "There is a lot of fancy methodology, but the macroeconomists get indigestion if you give them facts."

---

[4] As an example of the "Age of Quantification," George Stigler cites the sea of studies on regulatory practices and their costs and benefits in the past dozen years, where there was a vacuum before. He notes that thirty-six "quantitative studies of effects of laws" were reported in two journals alone during this period, the *Journal of Law and Economics* and the *Journal of Political Economy*. These are promoting a broader consensus within the profession, informing decision makers, and posing challenges that will make policy failures easier to identify. (Personal correspondence.)

> We are reminded *ad nauseam* that the "new economists" of the 1960's had promised to fine-tune inflation out of their full employment economy (a clear-cut triumph of caricature over fact since Keynesians time and again warned of precisely the opposite danger).

> Myrdal and Heilbroner have pointed to stagflation as Exhibit A that economists typically lag rather than lead their targets, that being "behind its time" is "the regular methodological weakness of establishment economics."

> Von Hayek recently reentered the fray to lay the blame for worldwide inflation squarely at the door of economists, particularly those "who have embraced the teachings of Lord Keynes."

Apart from the charge that Keynesian economists have *caused* inflation (which is much like saying that the cause of forest fires is trees), the bill of particulars against macroeconomics runs something like this: First, it did not forewarn the body politic that it would have to pay such a high price in endemic inflation for the attainment of high employment. Second, its progress in solving some important puzzles of endemic inflation relating, for example, to the Phillips curve, wage inflation, expectations, and uncertainty is much too slow. Third, there is no articulated general theory of inflation as such. Fourth, economists failed to foresee the 1973–74 epidemic inflation because their forecasting models lacked the central supply and price parameters. Fifth, macroeconomics is helpless in the face of epidemic or external-shock inflation—indeed, it has not satisfactorily explained the coexistence of inflation and recession, or stagflation. Without attempting a point-by-point assessment of these complaints, I will touch on all of them in the following sympathetic interpretation of how economists are coping with inflation's tough analytic and empirical challenges.

Addressing myself for a moment to our reproachful public, let me simply say to them: "We never promised you a rose garden without thorns." Over most of the past thirty years, macroeconomists have warned again and again, first, that aggressive fiscal and monetary policy to manage aggregate demand was bound to generate inflationary pressures once the economy entered the full employment zone, and second, that while full employment spells inflation, recessions run into price and wage rigidities that thwart deflation, an asymmetry bound to produce a ratchet effect on the price level. Keynes himself foresaw the basic problem in his little book, *How to Pay for the War*, in 1940. Abba Lerner and William Beveridge also wrote of the problem in the early 1940's. And it has been discussed in the stabilization theory and policy literature, in congressional hearings, and in other policy forums ever since.

This country finally embraced activist fiscal policies for full employment in the 1960's, most explicitly in the 1964 tax cut. Following the canons of Keynesian economics, focussing on the economy's full employment potential as their target, and steadfastly rejecting a spate of "structural" explanations of unemployment, economists were at first alone in prescribing tax cuts as a tonic for the stagnant economy. Enacted early in 1964, the tax cut delivered the promised expansion and budget balance without inflation. By August 1965, when Vietnam escalation began, unemployment had been brought to 4.4 percent with only the faintest stirring of the inflationary beast (i.e., with consumer prices rising at less than a 2 percent annual rate).

In a very real sense, economists have been victims of their own success. Macroeconomic policy, capped by the tax cut, was the major force holding the postwar economy on a vastly higher plane than the prewar economy.[5] On one hand, the high employment, limited-recession economy forged with our macro-economic policy tools is indeed an inflation-prone economy—the formula for successful management of high-pressure prosperity is far more elusive than the formula for getting there. Yet on the other hand, success bred great expectations on the part of the public that economics could deliver prosperity without inflation and with ever-growing material gains in the bargain. The message got through that we had "harnessed the existing economics . . . to the purposes of prosperity, stability, and growth," and that as to the role of the tax cut in breaking old molds of thinking, "nothing succeeds like success" (Heller). *The Economist* unkindly corrected me: "Nothing *ex*ceeds like success."[6]

To be sure, critics and converts alike ignored our caveats that the goal of "prosperity without a price-wage spiral" had "eluded not only this country but all of its industrial partners in the free world," that "the margin for error diminishes as the economy reaches the treasured but treacherous area of full employment . . . ," and that "the 'new economics' promises no money-back guarantees against occasional slowdowns or even recessions" (Heller).

All too soon, Vietnam blew the economy off-course. Economists found that in the political arena fiscal policy was not a two-way street and that the much delayed surtax adopted in mid-1968 was no match for surging inflation. Nor was the induced recession of 1969–70. It took a combination of the 1971 shock therapy of tight wage-price controls and the stimulus of tax cuts to subdue inflation and energize expansion. It is worth noting that economists analyzed and projected the effects of this "new economic policy" with exceptional precision. That the tax cuts, coupled with controls and devaluation, would generate a surging expansion at very moderate rates of inflation in 1972 was widely and accurately forecast.

But the period from August 1971 to January 1973 was in the nature of a remission from the inflationary disease, clearly not a cure. The 1969–70 recession brought home the worsening problem of persistent inflation in the face of slowdown and recession. It presented new empirical puzzles for the analysts of the Phillips curve, wage equations, and expectational inflation. And it began to prompt the public mutterings that are being intensified by the 1974–75 stagflation: "All right, so you did not promise us a rose garden without thorns—but the thorns without the rose garden?"

Keenly aware of these problems, economists have long been at the drawing boards on this problem of endemic inflation. In a close parallel with research on cancer, economists are working on various pieces of the inflation puzzle and producing useful insights and guidance for policy purposes. But as economists, we would be the first to underscore that these puzzles are far from being fitted into an articulated and holistic theory of inflation. Inflationary analysis appears as an appendage to Keynesian and monetarist theories. But as yet, the Keynesian apparatus cannot tell us how any given change in aggregate demand is divided between changes in real output and changes in prices. Nor has monetarist theory unlocked the puzzle of how the effects of monetary changes are divided between output and price level changes. And no big breakthrough is in sight.

---

[5] As gauges of the contrast between prewar and postwar performance: unemployment averaged 18.8 percent in the decade of depression (1931–40) in contrast with 4.8 percent in the twenty-eight years since World War II; the prewar peak annual rate was 24.9 percent, the postwar peak was 6.8 percent. Annual real *GNP* dropped 30 percent from 1929 to 1933; since the war, mild declines have occurred only in three years (1949, 1954, and 1970), though 1974–75 may add two more. Consumer prices in 1940 were 18 percent below 1929; from 1948 to 1974, they increased 106 percent.

[6] Macroeconomists were not alone in their exuberance in the mid-1960's. On this rostrum a decade ago, George Stigler, after reviewing the great promises and early accomplishments of the "Quantitative Revolution in Economics," was moved to say, "I am convinced that economics is finally at the threshold of its Golden Age—nay, we already have one foot through the door. . . . Our expanding theoretical and empirical studies will inevitably and irresistibly enter into the subject of public policy, and we shall develop a body of knowledge essential to intelligent policy formulation. And then, quite frankly, I hope that we become the ornaments of democratic society whose opinions on economic policy shall prevail."

Does this mean that the economist has to stand mute in the meanwhile? Not at all. He is pushing ahead on the various pieces of basic research on the cancer of inflation and isolating and prescribing effectively for particular forms of the cancer even without having a complete explanation of the disease. Let me come back to the sustained and systematic research efforts on endemic inflation after examining the 1973–74 epidemic and the economist's responses to it. Since the epidemic is an over-layer on the endemic base, the distinctions won't be clear-cut—but they are nonetheless useful for viewing what the economist is able to contribute to policy.

The food-fuel price bulge generated over half of the 1973–74 inflation—and of economists' woes as well. Yet, it is asking a lot of economists to expect them to have foreseen that the oil cartel would quadruple oil prices, that the world would suffer widespread and successive crop failures, that the Peruvian anchovies would go into hiding, and that the Soviets would "solve our surplus grain problem" overnight.

Several unpleasant policy surprises also beset the inflation forecasters. First, just when a new rash of inflation was breaking out early in 1973, the reasonably effective Phase II controls were abruptly dropped in favor of the weak and ineffective Phase III. Second, six months later, after inflation had changed into a commodity-driven structural phenomenon involving a drastic readjustment of relative prices, the White House (to the pained surprise of economists inside and outside the administration) prescribed just the wrong medicine, a new wage-price freeze. A third policy surprise was that the dollar was allowed to sink like a stone: At its low point in the summer of 1973 (just before a substantial rebound), relative prices of imports had risen 10 percent in six months. About a quarter of the 1973 inflation has been attributed to these policy developments (see William Nordhaus and John Shoven).

It is worth noting that unexpected twists and turns of federal policy—which might be termed "internal shocks" in contrast with the "external shocks" of the food-fuel price explosion—are a continuing bane of the forecaster's existence. The about-face of the Federal Reserve in 1974 is another painful case in point. The sharp turn from ease to tightness in the first quarter of the year was a major factor in transforming prospects of recovery into recession in the second half of 1974. It is not quite clear why economists should be better at anticipating these shocks, especially the external ones, than society as a whole, or other professional specialists, or practical men of the world. Nothing in statistical methodology or economic science enables us to predict random shocks. What *can* be expected of us is that when they occur, we will spot them quickly, identify them, and analyze their significance for policy.

It is also worth remembering that democratic governments, by their nature, are pressure-responders rather than problem-anticipators. This carries two implications for political economists. On one hand, if an idea's time has not yet come, or if a problem has not yet become a crisis, the economist's call for action is likely to go unheeded. On the other, spotting emergent problems early can perhaps hasten an idea's time and alert the policy makers to impending danger.

Economists can more readily be faulted for being caught by surprise by the shortages of materials and primary processing capacity that caused the economy to bump against its ceiling sooner than expected and by the worldwide economic boom that put severe pressure on raw commodity supplies and prices. On the first point, we suffered both from information failure—the official capacity indexes simply did not reveal how close the economy was to its output ceilings—and from analytic limits. While identifying the causes, economists have been unable to pinpoint the relative significance of the shortfall of investment that began in the late 1960's, of underinvestment caused by price controls, of delays induced by environmental policies, and of the surge in foreign demand touched off by devaluation. However, I should add that the shortages problem is meat and drink for economists, and they are responding (especially in the energy field) with new analyses of price elasticities, investment needs, and the like. All of a sudden, price theory is back in vogue, and elasticities have replaced multipliers as the badge of a policy maker's *savoir faire.*

Delays in perceiving that the *U.S.* economic expansion was part of a worldwide upsurge can again be laid more to lack of an adequate information system than to any inability to understand the underlying principles. Still, a better sense of history and of the emerging worldwide imbalance between growing aspirations and growing incomes on one hand and inelastic resource supply and lagging technology on the other would have made us more conscious and cautious. We are considerably less likely to be caught by surprise in the future in view of the new worldwide data networks that are being developed by Project LINK at the University of Pennsylvania and by Otto Eckstein and his colleagues at Data Resources Incorporated (*DRI*).

Without absolving economists, one should apply this operational test: With proper foresight, would tighter monetary and budget policy have been able to damp inflation? It is worth recalling, first, that the full employment budget was making a swing of over $10 billion towards restraint between fiscal 1973 and fiscal 1974 (from a $2 billion deficit to a $10 billion surplus under the old 4 percent unemployment standard) and that monetary policy pushed interest rates into the double-digit region; second, that there was little that an aggregate demand squeeze could have done to push world commodity prices down. So the answer is clear: Even tougher fiscal and monetary policy would have had limited scope in holding inflation down.

This is not to deny that generating a larger full employment surplus would have been the prudent course in calendar 1973. But it is worth noting that to offset the food and fuel price explosions—which were triggered by forces largely immune to *U.S.* fiscal and monetary policy—would have required a ***reduction*** of 3 percent in all other prices. Such a target implies depression-inducing doses of fiscal and monetary restriction, an unthinkable "solution."

Looking toward the future, many economists draw the lesson not that one should keep the economy's motor idling, but rather that one should provide it with safety devices and heavy-duty shock absorbers, for example, stock-piling of foodstuffs, oil, and basic raw materials, careful tracking of commodity exports, distant early warning systems to spot shortages-in-the-making, and conservation and development measures to limit dependence on foreign raw materials cartels. In other words, it is a call for better planning, better data, and faster conversion of knowledge into policy.

Another criterion of economists' responses to inflationary shocks is how quickly they adapted (read, "disaggregated") their macromodels, large and small, to incorporate new supply and price parameters that had previously been judged of second or third order importance and hence relegated to Marshall's *ceteris paribus* pound. Some of the mongrel pups impounded there turned out to be full blooded huskies, for example, food prices, the exchange value of the dollar, oil and other raw material supplies and prices. At first most economists were slow and the big models sluggish in their responses. After all, for two decades prices had moved in tandem with wages, with a year-by-year percentage-point differential of $2\frac{3}{4} \pm 1$. So most models relied on wage trends, with some adjustment for productivity and capacity behavior, to give them a fix on price trends. Their eyes were on labor market indicators rather than commodity supplies, exchange rates, and the like. After some initial delays, the model builders scrambled to disaggregate, to build microelements into their macromodels. For example, *DRI* now has good stage-of-processing models that absorb the impacts of food and energy explosions. Price elasticities are being built into the macromodels to reflect the impact of massive relative price changes on the macrodimensions of the economy.

The whole experience reminds us of the role and limits of econometric forecasting models. First, the combination of computers, mathematics, and econometrics cannot produce the miracles that the uninitiated may expect of them—there is no way of replicating reality with its 3 million equations, all of them non-linear. Second, their indispensable function is to bring us closer to reality and help the mind manage the previously unmanageable—they permit us to release vastly more animals from the *ceteris paribus* pound than we could manage without these tools. Third, they have to be constantly adjusted to plug in common sense, adjust the length of the lags, and bring in new dimensions of the problem. Else, they will lock out things that a more judgmental approach would include, and will fail to respond quickly to changes in order of importance.

So the inflation-shock experience has brought home the need not just to watch supply but to watch *all* the pieces lest the model prevail over the mind, rather than having the model help the mind prevail over matter. The macro-stalactites have to reach toward the micro-stalagmites, and vice versa. I hope that metaphor is not a portent of the pace at which the advance toward macro-micro fusion will proceed.

Economists who use judgmental models have shown us how to be the master rather than the slave of the computer. A case in point was the early analysis (especially by George Perry) of the macro-impact of the oil price increases. A year ago, his work had already brought out the oil paradox—the *in*flation of costs and hence prices, leading to a *de*flation of aggregate demand—and had provided some estimates of both. The insight that some $15 to $20 billion of consumer purchasing power would be siphoned off into the hands of oil producers and royalty collectors without any early return to the economy in the form of demand for imports or investment goods had important implications for demand-management policy—implications that were ignored until severe recession was full upon us.[7]

---

[7] Late in 1974, Perry undertook a more searching econometric probe with the benefit of actual rather than projected oil price data and with the aid of the large

These important insights into the macro-economic policy implications of oil prices fit into the broader efforts of economists to disentangle the sources of the current inflation and identify the appropriate remedies. They differentiate among (1) excess demand, which had spent most of its force by early in 1974, (2) the price-wage-price spiral, which began to turn more rapidly in 1974, and (3) external-shock or special-sector inflation, in particular, the commodity-price surges that permeate the present inflation and account for its special character and ferocity.

The first responds rather readily to monetary-fiscal pressure, the second responds more reluctantly, and the third is highly resistant to the demand-management measures of any given country. For the second and especially the third types, therefore, high costs in unemployment and foregone output have to be incurred for small gains in curbing inflation. So the distinction is an instructive one for policy—even when the instructions are ignored. As we meet here tonight, the economic lessons that were so long ignored are being painfully driven home by severe recession and unemployment coupled with continuing inflation. A much-belated consensus that fiscal and monetary stimulus can now be undertaken with minimal inflationary risk is rapidly forming.

The economists' three-ply classification of inflation sources is also useful in driving home another point: In most *U.S.* inflations, consisting of the first two types, one person's price is another person's income, so that in spite of some reshuffling, there is no net loss in real income. Not so in 1973–75. Commodity inflation has transferred tens of billions of dollars of *real* income out of the pockets of urban consumers and wage earners into the hands of farmers and foreigners where it is beyond the reach of the collective bargaining process. From this, several important inferences can be drawn:

> Point for point, this inflation *cum* relative price changes is harsher in its impact than previous postwar inflations.
>
> In this "no-win" inflation, the wage earner's loss has not generally been the employer's gain; hence, if the wage "catch-up" process succeeds in recouping the *full* rise in the cost of living, much of the wage increase will pass through to prices and thereby give the wage-price spiral another self-defeating turn.
>
> It follows, as various economists urged throughout 1974, that tax cuts to bolster the real income of labor, if put in the context of a social contract, might well relieve some of the pressure for higher wages.

In this respect, today's situation contrasts rather sharply with the 1950–51 inflation when a similarly rapid run-up in world commodity prices was accompanied by a rapid rise in profit margins side-by-side with vigorous federal policies to boost capacity. The ensuing combination of ebbing world market prices and wage increases that could be granted without generating higher product prices resulted in a remarkable four-year period of price stability from 1952 to 1956.

A closely allied economic insight goes to the nature of the inflationary process. It

---

scale formal models. His analysis shows that the purchasing power loss had reached $37 billion (annual rate) by the third quarter of 1974 and that the rise in the deflator attributable to the oil price jump was 3.8 percent. His analysis embraced not only the real-income effect (the transfer of real income from consumers to producers), but also the monetary-policy effect (the reduction of the real value of the money stock and the rise in interest rates stemming from the highly inelastic short-run demand for petroleum products), the automobile-demand effect (higher saving), and the induced-inflation effect (the price-wage-price effect) of the oil price rise on the macroeconomy.

P954

explains in good part why inflation is so stubborn even in the face of overly restrictive monetary-fiscal policy and rapidly mounting unemployment and slack in the economy. It is the sharp run-up in *relative* prices of food, fuel, and imported goods—coupled with the downward rigidities of wages and prices—that is the key to most of our stagflationary malaise today.

These downward rigidities are a striking example of the way in which economic solutions create their own problems and move the economist relentlessly from one new frontier to another. Once macroeconomics gave governments the know-how and tools of modern demand-management to avoid depression, and once the public caught on that even recessions are essentially man-made—chiefly by That Man in the White House, whoever he is, together with the Congress and the Federal Reserve Board—it became part of the politics of survival to hold employment high and keep recessions in check. Absent the fears of mass unemployment and prolonged recession, the risks of not cutting prices and not accepting lower wages are minimized. Having put the Great Depression of the 1930's far behind us, will we therefore have to live with the Great Inflation of the 1970's?

Essentially, the economist answers that, given the ratchet behavior of wages and prices, the price level can only float upward to accommodate the massive relative price increases of oil, grains, certain raw materials, and imported goods. These sharp changes in the composition of supply touch off reverberating price increases throughout the economy as prices in the scarce-supply sectors become costs in the less-scarce ones. The reverberations go on —in substantial part independent of the state of aggregate demand and hence of monetary and fiscal policy—until the prices of the initiating goods have risen sufficiently farther than prices in general to accomplish the necessary realignment of relative prices. This is the process going on now. It takes time, but not forever. It has much to do with double-digit inflation, but it does not condemn us to Weimar Republic inflation.

Solow (1975) reminds us that the supply-shift phenomenon bears a close relationship to the demand-shift analysis of the creeping inflation of the mid-1950's. At that time, the parallel process was touched off by an investment boom that put excess demand pressures on capital goods industries even when there was no excess aggregate demand in the economy. Given the downward rigidity and cost-oriented nature of wages and prices in areas of excess market power, the price level had to float upward to accommodate those relative price changes (see Schultze (1959)).

John Dunlop and other economists have emphasized that there is a closely related phenomenon on the wage side known as "scale wages" or "wage relativities" or even a "just wage" (see Robert Hall and Michael Piore). If the relative wage scale is thrown out of kilter by an outsized wage settlement in one industry, the others will writhe, twist, and turn until the old relationships are reestablished. There is only one way the wage structure can move to accommodate this process: Up. Again, the process burns itself out only when a new equilibrium has been established on a higher plateau.

The policy implications of the supply-shift, demand-shift, and wage-shift insights are reasonably clear. One is the limited scope of repressive monetary-fiscal policy in coping with this process. Another is that the key to a successful wage-price policy for these circumstances is to establish and effectuate norms for the pace-setters and thus thwart the wage-wage and price-price spirals and the interacting wage-price spiral. Once the process is launched, the role of a wage-price watchdog with teeth would be to see to it that the adjustment process is a limited and straightforward one, not a leapfrogging sequence that will prolong the agony of adjustment. Again, understanding the economics of the process is the *sine qua non* for shaping the right policy to fit the particular type and phase of inflation that is beleaguering us.

Let me return now, before closing, to several of the abiding problems of endemic inflation that are engaging the attention and efforts of economists.

An important but elusive question for the policy maker concerns the costs of inflation. Can the economist tell him anything useful and definitive on this subject? Useful, perhaps. Definitive, no. First, the economist would remind him that people continually blame inflation for crimes it does not commit. They are sure that every increase in their pay envelope is a reward for merit, every increase in prices an inflationary theft. Especially pertinent to our present shock-spiral is the observation that people "blame inflation for changes in relative prices and in real incomes that stem from market forces that have nothing to do with the course of the general price level" (Edward Foster).

Second, studies show that in a typical *U.S.* inflation, the poor have gained more in jobs and incomes than they have lost in higher prices. But in the present inflation, prices have shifted sharply against the poor, and any initial gains they may have made in jobs and income in 1973 have been more than offset by the losses incurred in the deepening 1974–75 recession induced to fight inflation.

Third, at the rates of inflation experienced prior to the 1973–75 explosion, most economists find it difficult to believe that the costs of inflation—mostly in redistributional effects, but with some distortion in resource allocation—hold a candle to the welfare losses of substantial add-ons to unemployment. Fourth, however, when inflation reaches double-digit levels, the costs in terms of the social conflicts and tensions it generates and the uncertainties and loss of confidence in the dollar yardstick it may breed are important intangibles that economists cannot ignore, yet have not been able to quantify. We need to understand far more about what unsettles and upsets people about inflation, how this affects their economic behavior, and what economic costs result. Clearly, in an economy where inflation is endemic, the balance between its gains and losses deserves intensive further study.

Another important question is this: How much of the present run-up in prices of foodstuffs, oil, and raw materials is a transitory phenomenon, how much is a one-time shift to a new plateau, and how much represents a new upward trend? Economists have trained the guns of price theory and price elasticity estimation on these questions in the case of oil and several other basic materials. They generally come up with more optimistic answers for five to ten years hence than for the near-term. But much of the answer lies in geo-political, meteorological, and similar puzzles—for example, the effectiveness of oil and other raw material cartels, the pace of world population increases and income growth, and the possibility of a dry, cold phase in world weather—that lie largely or wholly beyond the reach of economic analysis.

What we do know is this: The 1950's and the 1960's were a period of gently declining or roughly stable world prices for raw materials or foodstuffs. Now, rising population, industrialization, income, and aspirations may put such pressure on the world's supply capabilities that while we are not nearing any Club-of-Rome ultimate limits, we may for some time exceed the speed limits of stable expansion. If so we may have passed an inflection point in the price trends of basic inputs to the economy (see Walt Rostow). The mild downward trend of the 1951–71 period facilitated the rise in real incomes of urban workers side-by-side with rising profits. If this trend is reversed, rising income claims will generate greater strains, and the Phillips curve tradeoff will take place around a higher inflation constant. Economic analysis of long-run supply prices of basic commodities using alternative assumptions regarding world political, weather, and economic trends could be a useful aid to rational economic planning.

Coming back into the domain of economics as such, one should take account of the important new thinking and efforts now being devoted to the continuing mysteries of industrial pricing policies and the role of fixed-rule (generally, mark-up) pricing as a shield against uncertainty. Answering the question of how, and how fast, supply-shifts in the auction markets or market-oriented sector are transmitted through the rule-determined sector—where certain relativities seem to be maintained in the structure of prices (and wages)—is essential to an understanding of structural inflation (see Piore).

In turn, this analysis will strongly influence thinking on government intervention in private wage-price and perhaps also supply-demand decisions. If the wage-price structure is indeed fairly rigid and if supply- and demand-shifts set off an inflationary spiral, the "natural market forces" will not readily make the necessary supply-demand adjustment in any case. Wage-price restraint or controls would not be supplanting some supple and efficient resource allocation mechanism, yet would insert a circuit breaker into the inflationary spiral. This view of the world would also suggest that government action to stimulate supply and suppress demand at certain pressure points in the economy might well pass the test of economic efficiency. In pursuing these questions and hypotheses, the economist will be laying a firmer conceptual and empirical foundation for specifying the areas and circumstances in which intervention may be the lesser evil.

One should not leave the subject of economists' contributions to analysis and prescription on the inflation problem without mention of the intriguing attempt of the Brookings Panel on Economic Activity to bring the best analytical and empirical efforts of economists to bear directly on the problems and puzzles that confront the policymaker. In relation to inflation, the Panel has focussed much of its attention on such questions as the structure of labor markets, the Phillips curve relationship and wage equations, the costs of unemployment, price behavior in specific sectors like foodstuffs and oil, and the role of fiscal and monetary policies. Apart from the significant contributions that have been made to understanding these problems, and to bringing academic work into closer contact with current policy problems, the Brookings Panel is an interesting and perhaps unique exercise in "continuing confrontational econometrics." Responding to the kinds of criticisms quoted earlier in my remarks, the Brookings Panel combines rigorous quantitative testing with continuing surveillance by one's peers to assure that the investigator (a) looks beyond mathematics and makes his assumptions and relations conform to common sense, (b) spells out the implications of his econometrics and, if they are implausible, tries again, and (c) constantly keeps asking questions of the model. With the Panel now going into its sixth year of thrice-yearly meetings, previous analyses become not undisturbed museum pieces, but grist for the mill of constant retesting under the harsh light of reality and peer-group criticism.

I have dealt at some length with the substance of economists' work and findings on inflation because mere assertions of progress would hardly suffice to demonstrate what's right with economics in this most vulnerable area. The fact that there are no final or comprehensive answers has not kept economists from making significant distinctions, analyses, and measurements that equip policy makers with better means of judging the policy tradeoffs and determining how to improve the fit of policy-to-problem for the different types and stages of inflation. When policy makers fail to heed these lessons, as in 1974, both the economy and the economist feel the backlash.

Throughout this discourse, I have time and again been tempted to kick over the traces I fastened on myself and give voice to my own criticisms, dissatisfactions, and admonitions. But since an unholy (and unwitting) alliance of my colleagues and outside critics has amply and ably taken care of this, I felt it best to stay within my constraints in the interest of doing what I could do to redress the balance. As economists, we have many sins, none deadly, to confess. But these are far outweighed by the virtues, all quite lively, that we can legitimately profess.

Supply and Salary Adjustments to the Changing Science Manpower Market: Physics, 1948-1973

By R. B. FREEMAN*

The collapse of the science manpower market in the late 1960's raises important questions about the way in which high level labor markets adjust to sharp changes in economic conditions. What happens to salaries when demand for specialists declines greatly? How does the supply of new entrants respond to market ups and downs? What are the implications of the adjustment process for future manpower developments and current methods of manpower forecasting?

This paper examines these questions with respect to physics, which, as one of the first specialties to undergo the turnaround from relative shortage to surplus, offers an especially fruitful case for study. It finds real salaries and the supply of new entrants to physics to be highly sensitive to market conditions. Economic responsiveness critically affects the likely future state of the field and should be taken into account in the standard forecast methodology (see Alan Cartter). Section I outlines the principal post-World War II changes in the physics manpower market, the phenomenon under investigation. Section II analyzes the supply behavior of students and the determination of physics salaries in the framework of a recursive market model (see the author, 1971). The estimated model is used to forecast the future state of physics manpower, yielding strikingly different results from those obtained by standard techniques (see Cartter). These differences highlight the sensitivity of the labor market as an allocative device and the critical role of supply and demand adjustments in manpower analyses.

I. The Physics Job Market

The 1960's turnaround in the state of the physics labor market was marked by three important developments. First, as depicted in Figure 1, there was a substantial change in the flow of students into the field, with large and increasing numbers choosing physics in the late 1950's-early 1960's and fewer entering in the late 1960's. Panel A, which records the number of physics degrees relative to total male degrees from 1948 to 1972, shows, for example, that the relative number of B.S. degrees in physics rose in the 1950's to a peak of 1.84 percent in 1962 and then dropped nearly in half to 0.96 percent in 1972. Ph.D. degrees in the field plummetted downward from 6.7 to 4.6 percent of the total in the late 1960's (1967–72) and declined absolutely at the onset of the 1970's (−7 percent from 1970 to 1972). M.S. degrees followed a pattern similar to that of B.S.s and Ph.D.s, peaking in 1964, just two years after the B.S. peak and three years before the Ph.D. turning point.

The ratios of undergraduate enrollments

Enrollments, American Institute of Physics, Pub. R-151.10 (1973).

FIGURE 1

in physics to the population of prospective enrollees in panel B reveal even more striking changes in the supply of students between the 1950's and 1960's. At the undergraduate level, the proportion of male freshmen selecting physics in their junior year rises from 1.24 percent in 1953 to 2.31 percent in 1960 and then drops to a postwar low of 0.99 percent in 1972. Despite a near doubling in the number of undergraduate males, junior and senior year physics majors decline from 14,900 (1961) to 11,400 (1972). Graduate enrollments, having increased from 3.00 percent of all male graduate students in 1955 to 4.14 percent in 1961, trend downward sharply to 1.73 percent in 1972 with a 24 percent drop in absolute numbers at the end of the 1960's. First-year graduate enrollments, an especially sensitive measure of the adjustment margin of physics supply, fall by a third from 1961 to 1972 and decline sharply even when compared to the decreasing number of B.S. graduates. In short, there were large changes in the supply of students to physics in the postwar period, with the upward trend of the 1950's arrested and reversed in the 1960's.

The second major development was a significant fall in real salaries during the period of market downturn, after a decade or so of substantial increases in salaries. This sharp change in the economic status of physicists is examined in Table 1, which records percentage changes in physics and other salaries or earnings for various subperiods since World War II. While the patterns of change vary somewhat depending on the source of the data or the level of training, a reasonably clear picture emerges of physics salary developments.[1] During the 1954–62 period encompassing Sputnik (October 1957) and the Research and Development (*R&D*) boom, the salaries of Ph.D. and M.S. physicists, who constitute the bulk of the profession (80 percent), and the starting salaries of B.S. physicists (but not the annual earnings reported by the National Science Foundation (*NSF*)) increased more rapidly than those of comparison groups. After 1962, by contrast, the rate of change of physics salaries fell increasingly behind that in male professional earnings, annual earnings of full-time employees, and average hourly earnings. Between 1962 and 1968, physics Ph.D. earnings increased by 22 percent, M.S. earnings by 26 percent, and B.S. earnings by 25 percent compared to a 36 percent gain for male professionals. At the end of the 1960's and the onset of the 1970's, the income position of physicists declined more rapidly, with real as well as relative salaries falling. American Institute of Physics (*AIP*) surveys show, for example, no gain in starting Ph.D. and M.S. salaries and a 5.8 percent decline in B.S. salaries in the 1970–72 period when consumer prices advanced by 12 percent; College Placement Council (*CPC*) data show rough stability in money salaries over the same period and into the 1973 recruitment season. The net effect of this decline is to reduce relative physics earnings to pre-Sputnik levels or lower: in 1954 the premium of Ph.D. physics earnings over male professional earnings was 58 percent; in 1962, 89 percent; by 1970, it had fallen back to 57 percent. From 1970 to 1972 the ratio of *AIP* starting rates to professional earnings records a further drop of 12 percentage points (1.25 to 1.13). It is apparent from these changes that relative salaries in physics have been highly sensitive to market conditions and roughly as responsive to market declines as to booms.

---

[1] The major difference by level of training is the rapid increase of M.S. and B.S. salaries between 1951 and 1954 compared to the slow increase in Ph.D. salaries. The major difference by source of data is between B.S. salaries reported by the National Register, which increases only moderately from 1951 to 1962, and those of starting physicists reported by placement offices, which increase rapidly in that period.

Third, there was a sizeable shift in federal expenditures on basic research and development, atomic energy, and graduate training which had an exceptional impact

on physics and other scientific specialties. This shift appears to be the chief cause of the downturn in the science market (see the author, 1972b). Table 2 summarizes data pertaining to federal spending and activities that have impinged on physics in the 1950's and 1960's. Line 1 shows the postwar fluctuation of total *R&D*: the 1950's spurt in expenditures, the 1960's levelling of the rate of increase, and the 1968–72 decline in real and relative spending. A similar pattern is displayed in lines 2–5, which deal with activities more directly linked to physics: federally funded physics research (line 3), physical science basic research (line 4), percentage of physicists with federal support (line 5), and Atomic Energy Commission spending, which turns down in 1962 (line 2). Federal fellowship aid (lines 6–7) underwent a different path of increase and decrease, with the number of awards growing rapidly from 1962 to 1968 and declining thereafter. Because federal fellowships declined after the expenditure plateau, students supported in the 1960's graduated during the spending decline of the early 1970's, contributing to the manpower crisis of that time.

The turnaround in the market for physicists and other scientific specialists described above and the impending "demographic crunch" on higher education have spawned a crop of manpower requirements forecasts of the future (see Cartter, *NSF* (1971), Dael Wolfe and Charles Kidd) based on extrapolations of current and past developments. While useful in directing attention to possible supply/demand imbalances, the forecasts can be criticized for ignoring the effects of salaries and economic behavior on market developments,[2] possibly leading to erroneous or exaggerated statements of problems (see

---

[2] It should be stressed that the well-known Cartter forecast depends on a decline in the number of persons of college age in the 1980's, a relatively hard piece of evidence on which to base forecasts.

Glen Cain, the author, and Lee Hansen; the author and David Breneman). The degree to which forecasts are potentially misleading depends, all else the same, on the way in which the science manpower market adjusts to changes in economic conditions. How responsive is the market mechanism? Are supply and demand adjustments to economic incentives first- or second-order effects in manpower forecasts?

II. Market Adjustments and Forecasting in a Recursive Model

To answer these questions in the physics case, we analyze the observed pattern of change in enrollments, degrees, and salaries with a simple recursive model of the labor market and use the model to predict the number of Ph.D.s in the field in the 1970–80 decade. Variants of the model, which exploit the time delay in the production of graduates due to lengthy training periods to identify supply and demand adjustment processes, have been applied to other high level occupations with some success (see the author, 1971, 1972a,b, and forthcoming). In simplest form, focusing on starting graduates, the model contains a supply schedule linking the number of students entering a field to starting salaries and related incentives; a demand equation with the number demanded dependent on salaries and exogenous demand-shift variables;[3] and market clearing. Because of the lag in training specialists (upwards of 4–5 years for Ph.D. physicists), the number of new entrants depends on past market conditions and is predetermined with respect to the demand and market clearing equations. This makes salaries rather than quantities the appropriate dependent variable in the demand equation and creates a recursive "cobweb" structure that generates endogenous cyclical fluctuations. The recursive model differs greatly from the Arrow-Capron model of scientific markets wherein salaries, rather than supplies, react slowly to changes in the market. When, as seems reasonable, the disturbances in the supply and salary equations are independent, the equations are appropriately estimated by least squares.

Depending on data availability and the problems of concern, the model can be amplified to focus on the complexities of expectations formation (see Marc Nerlove, John Muth), adjustments in salaries due to bargaining during recruitment, decisions to complete as well as initiate training, interactions between the salaries and demand for younger and older specialists, and so forth. The current paper concentrates on the basic aspects of market adjustment: the responsiveness of students to market incentives, the factors determining starting salaries, and the "cobweb supply relation" which links supply to past levels of supply and demand. The cobweb relation, obtained by substituting the salary equation into the basic supply equation,[4] highlights the endogenous fluctuations that characterize the market.

A. *Supply Behavior*

The decision to study physics is examined in Tables 3 and 4 which relate (in *log* form) enrollments and degrees to salaries and a measure of alternative opportunities (male professional earnings). The salary variables are dated at the June preceding the date of enrollments used in the enrollment regressions and at the June 3,

---

[3] Selection of exogenous demand variables is difficult in analysis of factor demands. In the case of physics, federal *R&D* policies are taken as the major exogenous factor at work, making *R&D* expenditures exogenous.

[4] Formally, with the simple model

(1) $S = aW(-1)$ [Supply equation]

(2) $W = bS + cZ$ [Wage equation]

where S = supply, W = wages, Z = level of demand. Substituting we obtain

(3) $S = abS(-1) + acZ(-1)$ [Cobweb equation]

[e] Omitted 1960, 1961, 1963 due to absence of salary data for period of supply decision.

2, and 5 years earlier in the B.S., M.S., and Ph.D. regressions, respectively. Enrollments and degrees provide alternative, related measures of the same underlying supply behavior, with the former reflecting the immediate, and the latter, the ultimate impact of market incentives on the number of new entrants. The link between initial enrollments and degrees which results from the decision to complete a program (see the author, 1971) is not treated here due to the limited number of data points. The dependent variable in Table 3 is the proportion of students in physics; the dependent variable in Table 4 is the absolute number of students, yielding somewhat different estimating equations.[5] The starting salary variables are viewed as proxies for anticipated lifetime incomes, appropriately discounted. Lagged dependent variables are used to estimate the time delay in supply responses in the framework of a simple lagged adjustment model. Because we lack a continuous series of salaries in physics

---

[5] The equations differ because regressions with numbers as the dependent variables do not necessarily support the homogeneity postulate of the proportion regressions. Indeed, when the lagged number of physics students is entered in the regressions, the coefficient for all students becomes insignificant, and is dropped in the results shown in Table 4. As the homogeneity postulate remains a priori plausible, it was deemed fruitful to present the two sets of regressions.

TABLE 4—REGRESSION ESTIMATES OF PHYSICS ENROLLMENTS AND DEGREES 1954–72[a]

Equation	Dependent Variable	Constant	Physics Salaries	Professional Earnings	Lagged Number	R^2	S.E.E.
1)	Junior Majors 1957–72	3.46	1.15 (.50)	−.90 (.28)	.71 (.11)	.94	.06

3)	First-Year Graduate Students, 1954, 1960–72[b]	8.06	.87 (.60)	−1.04 (.30)	.42 (.38)	.81	.06
4)	B.S. Degrees, 1957–72	1.72	2.29 (.88)	−1.26 (.50)	.40 (.17)	.96	.04
5)	M.S. Degrees, 1956, 1959–72[c]	−1.10	.93 (.24)	−.27 (.36)	.67 (.10)	.99	.05
6)	Ph.D. Degrees, 1956, 1959–72[c]	−.68	.82 (.25)	−.42 (.38)	.83 (.11)	.99	.03

Source: See Tables 1, 2, and Figure 1, with salaries calculated by linking series as described in fn. 6.

[a] Dependent variables are the number of students at the level specified. All variables are in *log* form. Numbers in parentheses are standard errors of estimate.

[b] B.S. salaries in lines 1, 4; Ph.D. salaries in lines 2, 3, 6; M.S. salaries in line 5; all salaries deflated by the consumer price index. Salaries lagged 3 years in line 4, 2 years in line 5; 5 years in line 6.

[c] Omitted 1960, 1961, 1963, due to absence of salary data for period of supply decision.

over an extended time period, the calculations are based on a composite series obtained by linking overlapping *NSF*, *CPC*, and related data by least squares estimation.[6]

The computations of Table 3 reveal an extremely close relation between salary incentives and the number of physics students, suggesting that the ups-and-downs in supply shown in Figure 1 result from economically responsive behavior. Physics salaries obtain a sizeable positive coefficient in all of the regressions, and professional earnings a negative coefficient, often of similar magnitude. The salary variables account, by themselves, for three-fourths or more of the variation in the physics share of enrollments and degrees (odd-numbered regressions), with elasticities ranging from approximately unity (line 5) to over five (line 7). With the addition of the lagged endogenous variable, salary coefficients decline substantially (even-numbered regressions), indicative of different short- and long-run supply elasticities. Larger undergraduate than graduate elasticities presumably reflect the greater flexibility of persons not yet committed to science careers. The only divergent result in the table occurred in the Ph.D. regressions where an initial calculation relating the physics share to salaries lagged five years (consistent with the other lag patterns) yielded weaker results than that given in the table with the two-year lag,[7] suggesting substantial economic responsiveness in the decision to complete the doctorate program. As the physics doctorate typically takes four or five years to complete, the effect of salaries on the initial enrollment decision and on eventual graduation is likely to involve complex lag structures, on which our limited number of observations provides little light.

---

[6] Milton Friedman and Gregory Chow and An-loh Lin describe the optimal methods of extrapolation, interpolation, and linking series. In our case, the Ph.D. and M.S. series are obtained by regressing *CPC* (1960–73) data on *NSF* data (1951, 1954, 1957, 1960, 1962, 1964, 1966, 1968, 1970) and using the predicted salaries for the pre-1960 years in which *NSF* figures exist. The B.S. salary series is obtained by regression of *CPC* figures on a series obtained from the M.I.T. Placement Office for graduates of that school. All of the data are available on request.

[7] The regression with the five-year lag yielded a coefficient for physics salaries of 0.73, with a standard error of 0.48 and one for professional salaries of −1.42, with a standard error of 0.63.

Additional support for the economic interpretation of the changing supply of students to physics is given in Table 4, which focuses on the absolute rather than relative number in the field. Salaries are the key variables in these calculations, with the short-run elasticity of supply to physics salaries estimated at near unity for graduate students and over two for B.S. recipients. Interpreting the lagged dependent coefficients as adjustment parameters, the long-run elasticities of degrees to physics salaries range from 2.8 (M.S.) to 4.6 (Ph.D.) and 4.8 (B.S.). The summary statistics, high R^2, small standard errors of estimate, show that the simple supply model does a surprisingly good job in tracking the market turnaround, which suggests its value in forecasting.

B. *Provisos*

Although the calculations in Tables 3 and 4 support our analysis, they fall short of a "complete" explanation of supply developments in several ways. First, fellowship availability was omitted from the calculations due to the absence of data, with a potential bias on the estimated salary coefficients. The direction of the bias, which depends on the correlation of fellowships with supply (presumed positive) and of fellowships with salaries is unclear,[8] for the latter would appear to have been positive in the 1950's and early 1960's but negative during the period of greatest increase in fellowship support (1962–68). Second, the quality of physics students and programs has also been ignored, again with unclear consequences. In this case, while the less qualified are more likely to provide the adjustment margin in supply, high quality institutions (heavily dependent on federal *R&D* programs) have reduced enrollment more than low quality colleges and universities (see *NSF*, 1972a). Third, the simple lagged adjustment model is at best a crude first-order approximation to the underlying process of forming salary expectations and adjusting to new market conditions. Various alternative models allowing, say, for different lags with respect to physics salaries than to the broader professional earnings, have not been explored due to the lack of a complete salary series for the postwar period. Fourth, professional earnings have been used as a measure of the alternative opportunities facing students at various decision points, although in principle alternatives will vary by level of training.[9] These provisos notwithstanding, the evidence indicates significant student supply responsiveness to the changing science manpower market.

C. *Cobweb Supply Patterns*

An alternative perspective on supply behavior is given by the cobweb supply equation which links the career decision directly to the level of demand and predetermined numbers of graduates. The cobweb equation can be obtained, as noted earlier, by substituting the salary determination relation for salaries in the supply equation of the recursive model. It may also be obtained from a "job opportunities" model of career decisions in which opportunities depend on the balance between levels of demand and persons seeking work. Information about opportunities as well as salaries is likely to be useful in evaluating the current state of the market and in forecasting future possibilities. Deletion of salaries from the supply equation permits estimation in the absence of "good" salary data, which is especially fruitful in the case at hand.

---

[8] As Zvi Griliches shows, the omitted variable bias depends on the product of the least squares coefficients of the regression of the dependent variable on the excluded variable and of the regression of the included explanatory variable on the excluded variable.

[9] In theory, the alternative income affecting decisions will change each year as cumulated human capital increases. One experiment designed to provide a better measure of alternatives (which is possible with available data) is to treat B.S. salaries rather than professional earnings as the relevant alternatives to graduate students. This is, however, by no means optimal since many undergraduate majors do not view B.S. physics work as the proper alternative. Calculations with B.S. salaries support the results in the text. The regression of first-year enrollments divided by B.S. graduates on Ph.D. and B.S. salaries, for example, yields coefficients of 1.21 and −1.69, with standard errors of .93 and 1.23. The regression of the physics share of M.S. degrees on M.S. and B.S. salaries two years earlier yields 2.12 and −3.92 for the estimated coefficients, with standard errors of 1.04 and 1.32.

Table 5 contains estimates of the cobweb supply relation in physics for the postwar period. In these computations, enrollments or degrees are regressed on the lagged dependent variable, professional earnings, *R&D* spending (indexing the level of demand), and degrees in the year of the supply decision. In the degree regressions, the explanatory variables are lagged three (B.S., lines 1 and 2), four (M.S., lines 3 and 4), and five (Ph.D., lines 5 and 6)

[a] The dependent variable is the *log* of the number of degrees or enrollees, as specified. Independent variables are lagged by 3 years in lines 1 and 2; 4 years in lines 3 and 4; 5 years in lines 5 and 6; 1 year in lines 7–11. Numbers in parentheses are standard errors of estimate; all variables are in *log* form.

[b] B.S. graduates used in lines 1, 2, 7, 8; Ph.D. graduates in lines 5, 6, 9–11; and M.S. graduates in lines 3–4. Graduates with zero (0) lag are lagged the same number of years as other variables; graduates with (−1) lag are lagged an additional year.

[c] Adjusted *D.W.* statistic calculated by Durbin procedure which takes account of lagged dependent variable. The statistic is distributed, asymptotically, as the standard normal.

[d] Non-linear least squares estimates, with autocorrelation coefficients of −.66 (line 4), −.41 (line 6), −.24 (line 8), and −.76 (line 11).

[e] Omitted as insignificant; Standard *D.W.* statistic of 1.96 showed no serial correlation.

years, with graduates sometimes lagged an additional year. Precise determination of the cobweb cycles caused by the negative impact of degrees on enrollments is not possible due to collinearity between degrees one year apart. In some regressions, the table shows "best" results for graduates having the same lag as other variables (lines 3, 4, 10, 11); in other cases, an additional year lag does better (lines 5–9), while for B.S. degrees (lines 1 and 2), the cobweb effect is shared between the two. As evinced in lines 1 and 2, however, the estimated size of the effect is roughly the same regardless of the specific lag (adding the additional degree term in line 2 reduces the coefficient in line 1 from $-.42$ to $-.17$, increases its standard error, but gives the same total effect $(-.41=-.17-.24)$). Similar results are obtained for the other independent variables. More detailed investigation of autoregressive degree patterns confirms the basic results of the table (see the author, 1973b). Finally, the problem of negative serial correlation of residuals shown by the Durbin-Watson statistics adjusted to take account of the lagged dependent variable (see James Durbin) is treated in the non-linear least squares regressions of lines 4, 6, 8, and 11 where a one-period autocorrelation coefficient is estimated simultaneously with other coefficients, with little effect on the parameters of interest.

There are two important findings in Table 5. First, the key coefficient on graduates which must be negative by the model obtains the predicted sign in all regressions with especially large effects at the baccalaureate level (lines 1, 2, 7, 8) and for first-year graduate enrollments (line 9). The other explanatory variables are also accorded correctly signed and quantitatively plausible impacts on supply. Second, the regressions as a whole show that the cobweb relation provides about as good an explanation of degrees or enrollments as the supply regressions of Tables 3 and 4, with similar R^2 and standard errors of estimate.

D. *Determination of Physics Starting Salaries*

The demand or salary side of the market is investigated in Table 6 which displays regressions of physics salaries on the level of demand measured by *R&D* and numbers of graduates lagged one and two years. These regressions lend support to the recursive model with *R&D* having a substantial positive effect, and degrees a substantial negative effect on all three salary variables. As shown, *R&D* is accorded a larger effect on Ph.D. and M.S. than on B.S. salaries, presumably as a result of the greater concentration of *R&D* activity among higher degree recipients. The estimated coefficients have relatively small standard errors in regressions 1, 3, and 5 where only a single demand or supply variable is entered; addition of collinear variables in regressions 2, 4, and 6 reduces the coefficients and increases their standard errors, but (as in Table 5) preserves the sum. Hence the size but not the precise timing of the impact of *R&D* or degree on salaries is reasonably well determined: the elasticity of salaries to *R&D* ranges from .34(B.S.) to .54(M.S.) and the flexibility of salaries from minus .15 to .25.[10]

The regressions also provide information enabling us to evaluate the relative importance of demand and supply forces in the changes in physics salaries shown in Table 1. As the variance of *R&D* and degrees about their means turns out to be nearly the same in the period covered, the

---

[10] Note that the regression relates starting salaries to new entrants, not average salaries to total employment, and thus does not yield elasticities with respect to the stock of physicists. With ratios of graduates to employment of about 1 to 10, the flexibility coefficients for the entire stock would be ten times those in the text, which in turn implies that demand for all physicists is *inelastic*.

TABLE 6—SALARY DETERMINATION EQUATIONS[a] 1951–72

Equation	Dependent Variable and Time Coverage	Constant	*R&D* (−1)	*R&D* (−2)	Degrees (−1)	Degrees (−2)	R^2	*S.E.E.*

			(.26)	(.24)	(.16)	(.12)		

Source: See Tables 1, 2, and Figure 1, with salaries calculated by linking series as described in fn. 6.

[a] The dependent variable is starting salary of the specified group; salaries and *R&D* are in 1957–59 constant dollars. Dependent variables are lagged 1 or 2 years as specified (−1), (−2). All variables are in *log* form. Numbers in parentheses are standard errors of estimate.

[b] The years 1952, 1953, 1955, 1956, 1958, 1959, 1961, 1963 are omitted due to absence of salary data.

larger *R&D* parameters in the regressions implies that changed demand, due primarily to changes in federal *R&D* spending,[11] was the *chief source* of changes in physics salaries, though movements along the demand schedule due to supply developments are also significant.

E. *Market Adjustments and Forecasting*

To what extent do the preceding findings, which depict a highly responsive market adjustment process, lead to forecasts of future developments and problems that differ from those obtained by standard projection techniques? Table 7 contains predictions from the recursive model and other studies showing a marked divergence in forecasts, with strikingly fewer physics Ph.D.s anticipated for the future in our model than in even the lowest standard projection. More precisely, the table uses two versions of the estimated model to generate forecasts. Variant A employs the supply of Ph.D. degrees equation from Table 4 (line 6) and the Ph.D. salary equation from Table 6 (line 5) to generate forecasts. Since the degrees lag salaries by 4 years, predicted salaries are not needed until the 1977 degree forecast. Variant B replaces the degree equation with an equation determining first year enrollments (Table 4, line 3), assuming a similar percentage increase in Ph.D.s as in initial enrollments. In both models, *R&D* is assumed to increase at the postwar rate of growth of real *GNP* (3.7 percent) so that the *R&D* to *GNP* ratio is fixed; professional earnings are postulated to increase at their postwar trend level of 2.8 percent per year.

The important finding is that regardless of the precise equations used, our model predicts sizeable declines in physics doctorates while the other analysts foresee large increases. According to the recursive model, reductions in the supply of new

---

[11] Evidence regarding the effect of federal *R&D* on total *R&D*, which shows much greater variance in the former than the latter, is given in the author (1972b).

TABLE 7—ALTERNATIVE FORECASTS OF PHYSICS PH.D.S 1970–80

Years	Office of Education	Cartter	*NAS-NRC*	Model A	Model B
1969–70[a]	1500	1500	1500	1500	1500
1974–75	2153	1853	2153	1134	1189
1979–80	2492	2654	3350	731	786

Source: Office of Education, Cartter, *NAS-NRC* from Cartter; Models A and B, from the recursive model of Tables 4 and 5, as described in the text.

[a] The various projections use different base year numbers of Ph.D.s due to differences in the source of data. National Academy of Science-National Research Council (*NAS-NRC*) data differ somewhat from those of the Office of Education. I have set the base year number as 1500 and made projections on the basis of implicit percentage increases in the actual forecasts.

entrants will ameliorate physics market problems; according to the standard calculations, increases in supply will exacerbate the potential imbalance of the 1980's due to the likely fall in demand for faculty. While different changes in exogeneous variables such as a sudden sharp increase in federal *R&D* spending on energy would significantly invalidate our forecasts, it is evident from Table 7 that economic responsiveness has a first-order effect on the market and should be taken into account in manpower analysis.

III. Summary

The principal findings of this study can be summarized briefly:

1) The number of physics students has varied greatly in the postwar period, declining in the recent collapse of the science market after a decade of rapid increase. These changes result from economic responses to salary or job opportunity incentives, with fairly large elasticities of supply for physics salaries ranging from about unity in the short run to 3 or 4 in the long run at the graduate level, and from 2 in the short run to 4 in the long run for B.S. recipients.

2) Salaries of physicists have fluctuated significantly relative to other wages and salaries, rising in the post-Sputnik boom period and falling rapidly in the late 1960's and early 1970's. The bulk of the change in salaries can be attributed to *R&D* expenditures and the *R&D* policies of the federal government, with changes in supply having a smaller, though significant, effect.

3) Developments in the physics market, as in several other high level labor markets, appears to be well described by a simple recursive model which exploits the time delay in supply due to lengthy training programs. As a result of the recursive structure, large numbers of physics graduates create a market setting likely to reduce enrollments and future degrees in the field in accord with the cobweb scenario.

4) In the absence of a sharp increase in demand in the near future, market adjustments, especially on the supply side, are likely to lead to far fewer Ph.D.s in physics than indicated by standard forecasts. While the market still faces the major shock of a demographic-induced decline in demand for faculty in the 1980's, supply and salary adjustments will provide an important buffer to the decline.

The Balance of Payments and Money Supply Under the Gold Standard Regime: U.S. 1879-1914

By BIJAN B. AGHEVLI*

This paper analyzes the interaction between the real and monetary sectors via the balance-of-payments adjustment mechanism. An explicit theoretical model is developed and its coefficients are estimated (using two-stage least squares) for the United States during the period 1879–1914. The model is then synthesized to evaluate the views of Phillip Cagan, Milton Friedman and Anna Schwartz on one hand, and Jeffrey Williamson, Robert Mundell, and Moses Abramovitz on the other.

The period 1879–1914 in American economic history is of particular interest as it provides an excellent testing ground for theories pertaining to balance of payments and money supply. In this era the *U.S.* economy developed rapidly under a gold standard regime with little direct government intervention. There are conflicting interpretations of the events of this period with regard to the interaction between the monetary and real sectors.

Cagan and Friedman and Schwartz regard the variations in the money supply as independent of the changes in the real sector. Their view can be best summed up in the following passage from Friedman and Schwartz:

> One thing is abundantly clear from our narrative. Monetary changes have in fact often been independent, in the sense that they have often not been an immediate or necessary consequence of contemporaneous changes in business conditions.
>
> The clearest example is perhaps the monetary expansion from 1897 to 1914, which was worldwide and reflected an increased output of gold. The increased output of gold was partly a consequence of earlier decades of declining prices, which encouraged gold production, and so speaks also for a mutual interaction between monetary and economic changes. But clearly the monetary expansion cannot be attributed to the contemporary rise in money income and prices. By itself, the rise in money income and prices made for reduced output of gold in the world at large and for an outflow of gold from any single country in a gold-standard world. If the common movement of money and income was not purely coincidental, the direction of influence must run from money to income. [p. 686]

Cagan and Friedman and Schwartz, however, ignore the impact of changes in business conditions on the money supply via the balance of payments. In their analysis, they emphasize only the links between the balance on current account and prices, and treat the flows of capital along with the flow of specie as the passive part of the balance of payments. Thus, they ignore the effects of domestic real factors on the balance on current and capital account.

On the other hand, Williamson (1964) argued that variations in the money supply were linked to variations in the real sector through the balance of payments. He proposed that the variations in the balance of payments of the United States for the period 1879–1900 were dominated by capital movements, which in turn were caused by different rates of growth in the United States and Great Britain. Thus, the Williamson thesis specifies causation to run from rapid pace of development in the United States and more profitable investment opportunities to placement of securities in London, a capital surplus and gold inflow. Mundell's view of the relationship among the real sector, balance of payments and money supply is also along the lines proposed by Williamson. Mundell states:

---

* International Monetary Fund. I am indebted to George Borts, James Hanson, Jerome Stein, and Moses Abramovitz, who contributed many valuable comments and suggestions.

> The procyclical variation of interest rates in the United States causes after allowance for cycles abroad, a procyclical movement of the capital account which is usually associated with an anticyclical fluctuation of the trade-balance surplus. This appears to have been the historical pattern for the United States whenever it was not offset by cycles in the rest of the world. The capital account has dominated the trade balance procyclically and led to American payments surpluses in booms and deficits in depressions (the post-devaluation years, 1936–40, are an exception). Because the demand for money is procyclically strong it is associated with an excess supply of securities or goods, leading to a surplus on capital account, the trade balance, or both. [p. 7]

The relation between income, money supply, and balance of payments is explored in more detail by Abramovitz. He maintains that: "A more satisfactory treatment must recognize not only the impact of income change on the current and capital accounts; but it must also incorporate the effects of exogenous changes in the current and capital accounts on income and so on one another" (1973, p. 6). Abramovitz proposes that under a gold standard, the growth of money income and money supply is only possible through an *ex ante* (but not *ex post*) tendency in the economy to yield a balance-of-payments surplus. He is also in close agreement with the view that the developments in the real sector and domestic prices of real and financial assets had a strong impact on the balance of payments and consequently on the money supply. The main issues to be resolved, then, are the extent to which variations in the real sector influenced the trade and capital accounts, and whether the procyclical variation of capital inflows dominated the anticyclical variations of the trade balance.

In the following sections, an econometric model is constructed in which the relationships for the real and monetary sectors are specified. By estimating the coefficients of the model it is possible to determine to what extent the changes in the monetary sector were caused by the changes in the real sector. While the results support the view that capital flows move procyclically, they contradict the proposition that the procyclical movements of capital inflows dominated the anticyclical movements of the trade balance for the period under study.

I. The Model

In this section a two-country model is developed where each country produces one good. Goods can be exported or used for domestic consumption and business investment. Prices are determined by the conditions of equilibrium in the home and foreign goods markets. International movement of securities (bonds) is free, and bonds are assumed to be perfect substitutes regardless of nationality. As a result, there is a single rate of interest r which is determined by the condition of equilibrium in the world bond market.

The following notation is used for the two countries. The subscript f denotes the corresponding variable referring to the foreign country.

Y = real income
C = real consumption

I = real investment
S = real saving
P = price level
R = level of international reserves
r = nominal rate of interest
B_c = balance of trade
B_k = balance on capital account
M^D, (M^S) = nominal stock of money demanded (supplied)
XP = nominal exports

The following adjustment process, then, is assumed for the home and foreign price levels, world rate of interest, and level of international reserves. The operator D denotes time derivative and the coefficient λ_i is the speed of adjustment.

(1) $DP=\lambda_1$ {excess demand in the home country's goods market}
$$=\lambda_1\{IP-SP+XP-X_fP_f\}$$

(2) $DP_f=\lambda_1$ {excess demand in the foreign country's goods market}
$$=\{I_fP_f-S_fP_f+X_fP_f-XP\}$$

(3) $Dr=\lambda_3$ {excess supply in the world bond market}
$$=\{IP-SP+M^D-M^S+I_fP_f-S_fP_f+M_f^D-M_f^S\}$$

(4) $DR=$ {home country's balance-of-payments surplus}
$$=\{XP-X_fP_f+B_k\}$$

Derivation of the excess demand functions for home and foreign goods is quite straightforward.[1] Excess demand for bonds is derived by assuming that individuals save either by purchasing newly issued bonds or by adding to their money balances. Moreover, it is assumed that individuals adjust their holdings of money to desired levels by the purchase and sale of bonds, not goods. Excess supply of bonds in the world can be written then as the sum of excess of investment over savings and excess demand for money in each country.[2] (See equation (3).)

The level of international reserves will adjust as long as there is nonzero balance of payments according to equation (4). It should be noted that as long as any market is out of equilibrium, the rest of the system will also be thrown out of equilibrium. The balance of payments, therefore, will always reduce to zero at equilibrium. Furthermore, equilibrium in the goods and bond markets concurrent with zero balance of payments implies that excess demand for money in each country is also equal to zero. Consequently this system satisfies Walras' law (aggregate budget constraint), allowing the bond market to be dropped from view and replaced by the money market. Specification of the bond market, however, facilitates explanation of the way securities are traded between countries, and leads to a definition of the balance on capital account.

II. Balance on Capital Account

A country's balance on capital account is determined by its excess sale of securities to foreigners over its purchase of foreign securities. It is assumed that bonds are perfect substitutes for each other independent of the issuing country, and they are traded freely in what is called a world bond market.[3] In this framework, rates of interest at home and abroad will move together and interest rate differentials will not be observed. Thus, to the extent that the world interest rate is determined endogenously, the balance on capital account cannot be specified as a function of the interest rate differentials between the countries.

---

[1] For derivation of these excess demand functions and the stability analysis of the dynamic system, see the author and Borts.

[2] Assume that net flow demand for money, $m^d=K(M^D-M^S)$. For simplicity and with no loss of generality set the speed of adjustment K equal to unity. Excess demand for money is, then, given by the expression (M^D-M^S).

[3] It could have been assumed that the rate of return of foreign bonds for domestic residents is lower than r due to a "transfer" cost. However, as long as this cost is fixed and residents of each country view the other country's bonds to be as riskless as their own, this will not affect the analysis.

The domestic demand for foreign long-term capital inflows B_k^d is determined by the excess of new securities issued at home over the domestic financial demand. On the other hand, the foreign supply of capital inflow B_k^s is determined by the excess of foreign financial demand for securities over the foreign securities issued abroad. Thus, we can write:

$$(5)\quad \begin{aligned} B_k^d &= IP - SP + M^D - M^S \\ B_k^s &= -I_fP_f + S_fP_f - M_f^D + M_f^S \end{aligned}$$

Excess supply of bonds in the world bond market $\bar{E}$ can then be written as:

$$(6)\qquad \bar{E} = B_k^d - B_k^s$$

First, assume that the world bond market is in equilibrium ($\bar{E}=0$). This implies that the domestic demand for foreign capital inflows B_k^d matches the foreign supply of capital outflows B_k^s. That is, $\bar{E}=0$ implies $B_k^d=B_k^s$. In this case, the home country's balance on capital account B_k (B_k which is equal to the negative of the foreign country's balance on capital account) is given by either B_k^s or B_k^d.

$$(7)\quad \begin{aligned} B_k &= IP - SP + M^D - M^S \\ &= -I_fP_f + S_fP_f - M_f^D + M_f^S \end{aligned}$$

Depending on the lending or borrowing conditions of the home country at initial equilibrium, B_k could be negative, zero, or positive.

It is so far assumed that the world bond market is in equilibrium. The above formulation of the balance on capital, however, does not apply when the world bond market is in disequilibrium. In this case, there will be an excess supply (demand) for bonds in the world and $\bar{E}$ will be greater (less) than zero. Thus, the home country's demand for capital imports will exceed (fall short of) the foreign country's supply of capital. Clearly, as long as the world bond market is in disequilibrium, some individuals must remain unsatisfied. The question is, how do these unsatisfied demanders or suppliers of bonds distribute themselves between the two countries? Since it is assumed that people have free access to the bond market and they all regard all bonds as perfect substitutes, it is reasonable to conclude that unsatisfied individuals would be distributed at random between the two countries. Therefore, the home country's balance on capital account will be determined as a weighted average of the home country's demand for capital inflows and foreigners' supply of capital outflows. The weights would be determined by the size of the two economies and it will be assumed that once they are established they will remain unchanged.

Constraining the weights to add up to unity and denoting them by u and $(1-u)$, the home country's balance on capital can be written as:

$$(8)\quad \begin{aligned} B_k &= uB_k^d + (1-u)B_k^s \\ &= u[IP - SP + M^D - M^S] \\ &\quad + (1-u)[S_fP_f - I_fP_f + M_f^S - M_f^D] \end{aligned}$$

The above expression for the balance on capital account reduces to the previous formulation (equation (7)) at equilibrium. It should be noted that B_k could be a positive or negative function of the rate of interest depending upon the relative size of the two economies, as the following expression indicates.

$$(9)\qquad \frac{dB_k}{dr} = u\frac{dB_k^d}{dr} + (1-u)\frac{dB_k^s}{dr} \gtrless 0$$

In the above framework, the balance on capital account is ultimately determined by the equilibrium condition of the bond market. What, then, determines the long-term changes in capital flows? Once the system is in equilibrium the balance on capital account will change only as a result of shifts in investment, savings, or demand for money at home and abroad. The rate of interest always adjusts to eliminate any excess demand in the bond market. In this context, the relation between the rate of interest and capital flows is based on the nature of these exogenous shifts. Therefore, capital flows cannot be estimated as a function of the interest rate due to obvious identification problems. This could explain the failure of many empirical studies to identify a positive relationship between the interest rate and capital flows.

To verify the above analysis empirically, it is assumed that Great Britain was the only source of capital imports of the United States. This is not an unrealistic assumption as Great Britain was the main creditor of the world, and London was the major capital market in this period. Therefore, the British excess demand for bonds could be taken as a good proxy for the foreigners' supply of capital to the United States.

For the moment, the assumption is made that nominal investment $\bar{I}P$ is composed of two parts. The first part is denoted by $I(r)$ and represents that portion of the investment which responds to variations in the nominal interest rate. The second part, IP, represents that portion of investment which shifts exogenously due to growth factors. Also assuming that the money market is in equilibrium, domestic financial demand for securities is simply given by nominal savings. Then, writing the interest elastic portion of the *U.S.* investment $I(r)$ and the normal savings SP as linear functions of the interest rate and nominal income, and assuming that analogous relationships hold for the United Kingdom (and subscripted appropriately by f), the following relationships are derived:

$$(10) \quad I(r) = i_1 - i_2 r, \qquad i_2 > 0$$

$$(11) \quad SP = s_1 + s_2 r + s_3 YP \qquad s_2, s_3 > 0$$

Then

$$\begin{aligned}(12) \quad B_k^s &= \bar{I}P - SP = IP + I(r) - SP \\ &= (i_1 - s_1) - (i_2 + s_2)r + IP \\ &\quad - s_8 YP\end{aligned}$$

and analogously

$$\begin{aligned}(13) \quad B_k^d &= -\,(\bar{I}_f P_f - S_f P_f) \\ &= -\,[I_f P_f + I_f(r) - S_f P_f] \\ &= -\,(i_1' - s_1') + (i_2' + s_2')r \\ &\quad - I_f P_f + s_3' Y_f P_f\end{aligned}$$

Assuming that the rate of interest varies to equilibrate the bond market, the following reduced form equation for capital flows is derived by eliminating the interest rate.

$$\begin{aligned}(14) \quad B_k &= b_1 + b_2 IP - b_3 YP - b_4 I_f P_f \\ &\quad + b_5 Y_f P_f\end{aligned}$$

where $0 < b_2, b_3, b_4, b_5 < 1$.

In order to estimate the above equation,[4] Abramovitz's index of nominal construction for the United States and Alexander Cairncross' British investment series are used as proxies for IP and $I_f P_f$, respectively. It should be recognized that the Abramovitz construction series is not a completely satisfactory proxy for aggregate *U.S.* investment. In the absence of any other meaningful investment series however, the choice of this proxy is a forced one. Moreover, to the extent that railroad investment was the major vehicle for capital imports in this period and the movements of the Abramovitz index closely paralleled those of railroad investment, there is more justification for using the above series in estimating capital flows. As the following regression indicates, all of the parameters have the predicted signs and are significant at 1 percent confidence level, except the Y_fP_f term which has the predicted sign but is not significant. The t-values are given directly below the coefficients.

---

[4] Since separate data for long- and short-term capital are not available prior to 1900, B_k includes both categories for this period. For the description of other series used, see the Appendix.

$$(15)\quad \begin{aligned} B_k = {} & 346.1 + \underset{(3.1)}{\underset{(3.1)}{}} \underset{(3.1)}{0.088IP} - \underset{(2.9)}{0.024YP} \\ & + \underset{(0.25)}{0.042Y_fP_f} - \underset{(4.6)}{0.0053I_fP_f} \end{aligned}$$

$$\bar{R}^2 = .76 \qquad D.W. = 2.03$$

It should also be noted that the $U.S.$ and British investment series were not detrended or smoothed out by averaging procedures in order to guarantee that they reflected all the short-term oscillations in the pace of economic activity.[5]

III. The Balance on Trade Account

The balance on trade account is specified by introducing the export and import functions. Given that the United States' demand for imports was only a small fraction of the total world demand, it did not affect import prices appreciably. Thus, it is assumed that the $U.S.$ imports were determined according to the demand schedule and import prices were determined exogenously. Assuming that import goods are used for consumption and investment and specifying the demand for consumption goods as a linear function of nominal income, the demand for nominal imports ZP_z is estimated as follows:[6]

$$(16)\quad ZP_z = \underset{(6.4)}{2.49} + \underset{(3.6)}{0.097IP} + \underset{(2.2)}{.015YP}$$

$$\bar{R}^2 = .93 \qquad D.W. = 1.38$$

In the above formulation, it is assumed implicitly that investment influenced imports independently of income. It is argued that even though investment and income moved parallel to each other in the long run, their movements did not closely coincide in the short run. In fact, during business expansions, investment absorbs such a large share of output that imports rise by much larger amounts than the rise in output would suggest.

Next, the demand for and supply of exports are considered. Export prices, unlike import prices, are determined endogenously in order to equilibrate the foreign demand for and the domestic supply of exports. Supply of real exports X^S is specified as a positive function of the ratio of export prices P_x to the domestic price level P. Moreover, the export sector grew along with the rest of the economy due to the growth of capital stock, the labor force, and technological advancements. Using the level of the real output Y as a scale factor,[7] the supply of real exports is:

---

[5] Alternatively, Williamson (1963) has used Ulmer's series of net capital expenditures on American railroads $I'_{U.S.}$ as a "pull factor" and the Cairncross' series of British home investment as a "push factor" to explain the inflows of capital K. Using trendless annual data, smoothed by a moving five-year average, he obtained the following regression results for the period 1871–1914 (standard errors are given below the coefficients):

$$K = 914 + \underset{(0.20)}{0.03\, I'_{U.S.}} - \underset{(0.16)}{8.84\, I'_{G.B.}} \qquad R^2 = .65$$

Williamson's statistical methods of using five-year moving averages of detrended data were challenged by J. Ernest Tanner and Vittorio Bonomo. They maintained that "A simple five-year moving average may leave many cyclical influences in damped form and induce spurious correlation of its own" (p. 47). Tanner and Bonomo proceeded to remove the cyclical influence by averaging the data over the National Bureau reference cycles. They concluded that their evidence " . . . shows no positive correlation between the rate of economic growth and the rate of net capital inflow" (p. 51). To the extent that capital flows react to short-term oscillations in the investment series, however, we should not use any smoothing or averaging procedures which eliminate these oscillations.

[6] The Durbin-Watson ($D.W.$) statistic falls above the upper bound margin (i.e., $d_u = 1.37$) which implies there is no serial correlation in equation (18).

[7] Alternatively, the stock of capital, the labor force, or a time trend could have been used instead of the

$$(17) \qquad X^S = f_0(P_x/P)^{f_1} Y^{f_2} \qquad f_0, f_1, f_2 > 0$$

The demand for real exports depends on the level of foreign income Q and the terms of trade (i.e., the ratio of foreign prices P_z to export prices P_x). Denoting the elasticity of foreign demand for exports with respect to foreign income and the terms of trade by g_1 and g_2, respectively, the demand for real exports is:

$$(18) \qquad X^D = g_0 Q^{g_1}(P_z/P_x)^{g_2} \qquad g_0, g_1, g_2 > 0$$

Assuming that the elasticity of demand for real exports with respect to the terms of trade, g_2, is equal to unity, nominal demand for exports can be estimated as a function of foreign variables alone (equation (18)). That is, the nominal demand for exports becomes basically a reduced form equation and can be estimated independent of export prices in the simultaneous system. Constraining the coefficient of foreign prices to unity ($g_2 = 1$) gives the following results:[8]

$$(19) \quad Log\,(XP_x) = \underset{(10)}{-\,2.64} + \underset{(21)}{1.13}\,Log\,Q + Log\,P_z$$

$$\bar{R}^2 = .93 \qquad D.W. = 1.20$$

The above assumption of unit elasticity of export demand with respect to the terms of trade is a strong assumption and should be supported with some empirical evidence. In order to provide this, the foreign demand for real exports (equation (18)) is estimated simultaneously with the supply of real exports (equation (17)), using two-stage least squares method.[9] The following results are obtained for estimation of equation (18).

$$(20) \qquad Log\,X = \underset{(9.4)}{-\,2.63} + \underset{(19)}{1.13}Q + \underset{(2.5)}{0.96}\,Log\,(P_z/P_x)$$

As the above results indicate, the estimated value for coefficient g_2 is not significantly different from one. Thus, the empirical results provide us with strong justification for assuming g_2 is equal to unity.

IV. Demand for Money and Its Composition

This period of American economic history was characterized by a rapid expansion of the financial sector. The development of banking facilities had two important effects on the amount of private monetized transactions. The first effect was the educational element which helped to familiarize the public with the advantages of engaging in monetized transactions. As banking facilities spread to the rural areas, they helped to popularize money as a more convenient means of transactions as opposed to barter trade. In addition, rapid expansion of new banks decreased the opportunity cost of monetized transactions relative to barter trade, particularly as banks became more conveniently located for people to use their services.[10] The number of banks is used here as an index of banking development, and is denoted by N. The amount of real per capita monetized transactions T can then be written as a function of real per capita income (Y/L) and the number of banks N, according to the following equation.

---

income variable. The value of real income, however, seems to be a more reasonable choice as it indicates that the export sector grew along with the rest of the economy.

[8] The $D.W.$ statistic falls in the indeterminant range. Correction for serial correlation, however, does not change the results appreciably as the following corrected regression equation indicates.

$$Log\,(XP_x) = 2.37 + \underset{(5.7)}{1.07}\,Log\,Q + \underset{(12)}{}Log\,P_z;$$

$$\bar{R}^2 = .94 \qquad D.W. = 2.09$$

[9] For a description of the data, see the Appendix.

[10] See Robert Barro, James Hanson, and Luis Rosas.

$$(21) \qquad T = T_0(Y/L)^{q_2}N^{q_3}$$

$$\frac{dT}{d(Y/L)} > 0; \quad \frac{d^2T}{d(Y/L)^2} > 0 \text{ implies } q_2 > 1$$

$$\frac{dT}{DN} > 0; \quad \frac{d^2T}{dN^2} < 0 \text{ implies } 1 > q_3 > 0$$

The first derivative of T with respect to income and the number of banks should clearly be positive. The second derivative of T with respect to income is assumed to be positive to indicate that as people's income rises, they engage in proportionally more monetized transactions. On the other hand, the second derivative of T with respect to the number of banks is assumed to be negative to indicate the diminishing returns associated with this variable.

The next step is to assume that individuals hold certain amounts of real balances m which they replenish periodically by shifting their assets from interest-bearing assets (i.e., bonds) to money. There are two types of costs associated with such shifts. First there is an opportunity cost associated with the foregone interest payments on interest-bearing assets. Second, there are certain transfer costs involved in shifting from bonds to money. These transfer costs are of two kinds: a fixed cost which can be viewed as the foregone opportunity cost associated with the inconvenience of going to the broker to make the transfer and an explicit cost (i.e., "broker" fees) which is determined by the amount transferred. By assuming that each individual chooses his average real balances m in such a way to minimize the total cost, it can be shown[11] that m is given by the following relationship:

$$(22) \qquad m = P_0 r^{-P_1}(Y/L)^{P_2}N^{P_3}$$

where $\frac{1}{2} < P_1 < 1$; $\frac{1}{2} < P_2 \simeq 1$; $\frac{1}{2} < P_3 < 1$. The coefficients $-P_1$, P_2, and P_3 denote the elasticity of real balances per capita with respect to the rate of interest, real income per capita, and the number of banks, respectively. The following regression[12] indicates that the estimated coefficients conform significantly to the values hypothesized in equation (23).[13]

$$(23) \quad Log\left(m = \frac{M}{PL}\right) = \underset{(5.3)}{-\,2.87} - \underset{(8.8)}{0.83}\, Log\, r + \underset{(6.8)}{0.94}\, Log\,(Y/L) + \underset{(6.6)}{0.40}\, Log\, N$$

$$\bar{R}^2 = 0.99 \qquad D.W. = 1.46$$

It should be noted that the above estimated demand for money function is quite interest responsive (i.e., the estimated interest elasticity is 0.83). Thus, these results directly contradict Friedman and other monetarists who contend that demand for money is not very responsive to interest rates.

So far, individuals' demand for money has been derived irrespective of the form in which it is held (i.e., deposits or currency). The individual's desired deposit-currency ratio is determined by the relative attractiveness of deposits and currency. Holding balances in the form of deposits not only provides people with a positive rate of return (banks in this period paid interest on demand as well as time deposits), but is also a safer method of holding balances and provides a permanent record of transactions. Individuals are forced to hold certain amounts of currency in hand since checks are not always acceptable in transactions. As the real income per capita rises, however, the percentage of transactions which can be financed by checks would rise. Thus, the deposit-currency ratio would be positively correlated with per capita income.

---

[11] For a theoretical derivation of equation (25), see the author.

[12] For the description of data used, see the Appendix.

[13] The *D.W.* statistic falls above the upper bound margin (i.e., $d_U = 1.44$) which implies there is no serial correlation in equation (25).

The other important factor contributing to the rise in the deposit-currency ratio in this period was the development of the banking sector. The rise in the number of banks not only increased the demand for money by familiarizing people with the advantages of checking, but also induced a shift in balances from currency to deposits by making banking services more accessible. The deposit-currency ratio, then, is estimated as a log-linear function of real incomes per capita and the number of banks, where deposits and currency are denoted by D and C, respectively.[14]

$$(24)\quad Log\,(D/C) = \underset{(12)}{-\,8.3} + \underset{(3.2)}{0.88}\,Log\,(Y/L) + \underset{(4.0)}{0.53}\,Log\,N$$

$$\bar{R}^2 = 0.91 \qquad D.W. = 0.91$$

V. Supply of Money

In this section the supply of money is specified under a fractional reserve system. Using the identity derived by Friedman and Schwartz, supply of money can be formulated in terms of its three determinants; namely, high-powered money (H), deposit-currency ratio (D/C), and the deposit-reserve ratio (D/R).

$$(25)\quad M^S = H\left[\frac{D/R(1 + D/C)}{(D/R + D/C)}\right] \equiv KH$$

$$(26)\quad K = \frac{D/R(1 + D/C)}{D/R + D/C}$$

TABLE 1

Proximate Determinants of the Money Supply	Changes in Money Supply Attributed to Changes in Indicated Determinants as a Fraction of Total Change (1879–97)	(1897–1914)
High-powered money	.66	.64
Deposit-currency ratio	.24	.13
Deposit-reserve ratio	.06	.17
Interaction of ratios	.04	.05

Friedman and Schwartz were able to identify the extent that each of the above determinants of the money supply contributed to its variations. Their results for the periods 1879–97 and 1897–1914 are summarized in Table 1.

The most important source of change in the money supply was high-powered money. Changes in high-powered money were, in turn, caused primarily by changes in the monetary gold stock (approximately 68 percent). Changes in the monetary gold stock were due to (a) the flow of international gold, and (b) the excess of domestic gold production over consumption (i.e., jewelry, arts and crafts, hoarding, etc.). Thus, high-powered money H can be written according to the following identity.

$$(27)\quad H = H_{t-1} + E + (G_p - G_c) + B$$

where:

H_{t-1} = high-powered money in the previous period
E = changes in nongold components of high-powered money (i.e., silver, national bank notes, treasury notes, etc.)
G_P = domestic gold production
G_c = domestic gold consumption
B = balance of international payments

Assuming that domestic gold consumption is determined exogenously, and letting

$$(28)\quad H_0 \equiv H_{t-1} + E - G_c$$

---

[14] The $D.W.$ statistic indicates presence of serial correlation. Correction of serial correlation, however, does not change the results significantly, as the following corrected regression indicates:

$$Log\,(D/C) = \underset{(6.4)}{-8.3} + \underset{(1.8)}{0.83}\,Log\,(Y/L) + \underset{(2.6)}{0.53}\,Log\,N;$$

$$\bar{R}^2 = 0.91 \quad D.W. = 2.07$$

We can write:

$$H = H_0 + G_P + B \tag{29}$$

The domestic production of gold G_p is influenced by technological advancements and new discoveries in the gold mining sector. Following the discovery of rich mines in California in 1848, there were no important discoveries of gold in the United States until 1887. Thus, the *U.S.* gold production declined slowly all through the 1880's. Around 1888, however, the production of gold started to rise again due to innovations in the purification of gold ore (i.e., use of chlorination process and cyanide of potash in the extraction process).[15] Moreover, one would expect to see a negative relationship between the domestic price level and gold production. As the price level rises (falls), the supply of gold should fall (rise) as its real price in terms of other goods falls (rises), (i.e., the nominal price of gold is fixed by the government). In order to substantiate the above relationship, the period is split into two intervals and a trend term is used to capture the secular fall in production due to the depletion of resources prior to 1890, and the subsequent rise due to the new discoveries and technological advancements after 1890. Estimation of gold production as a function of price level and a trend gives the following results:[16]

$$(30)\quad Log\, G_P = -\underset{(3.6)}{2.06} - \underset{(2.7)}{2.96}\, Log\, P - \underset{(3.2)}{0.057t} \qquad (1879\text{–}89)$$

$$\bar{R}^2 = 0.52 \qquad D.W. = 1.13$$

$$Log\, G_P = \underset{(2.3)}{0.98} - \underset{(4.8)}{2.14}\, Log\, P + \underset{(12.2)}{0.077t} \qquad (1890\text{–}1914)$$

$$\bar{R}^2 = 0.93 \qquad D.W. = 0.52$$

In addition to the variations in the gold stock, variations in the deposit-currency and deposit-reserve ratio also contributed to the rise in the money supply. Inasmuch as the changes in the deposit-reserve ratio were marginal, no attempt is made to explain them and it is assumed that this ratio is determined by the government and the banking sector exogenously. The deposit-currency ratio, however, is determined endogenously according to equation (24) derived in the last section.

VI. The Simultaneous Model

In the previous sections, all the structural equations have been estimated using single equation techniques. In order to guarantee that these equations are not misspecified and the simultaneous bias does not invalidate the results, the complete system is reestimated using two-stage least squares method. The system is composed of six structural equations which in addition to two identities determine all eight endogenous variables of the system, namely, XP_x, ZP_z, B_k, M^D, M^S, D/C, G_p, and P. The estimation results are given below:

$$(31)\quad Log\,(XP_x/P_x) = \underset{(10)}{2.64} + \underset{(21)}{1.13}\, Log\, Q$$

$$(32)\quad ZP_z = \underset{(6.3)}{2.49} + \underset{(3.6)}{0.099}IP + \underset{(2.2)}{0.015}YP$$

$$(33)\quad B_k = \underset{(3.1)}{343} + \underset{(3.0)}{0.087}IP - \underset{(2.9)}{0.024}YP - \underset{(4.6)}{5.29}I_fP_f + \underset{(0.28)}{0.047}Y_fP_f$$

$$(34)\quad Log\frac{M}{PL} = \underset{(5.3)}{2.87} + \underset{(6.8)}{0.94}\, Log\frac{Y}{L} + \underset{(6.6)}{0.40}\, Log\, N - \underset{(8.8)}{0.84}\, Log\, r$$

---

[15] See Cagan, p. 59.

[16] The *D.W.* statistic indicates presence of serial correlation. Since the trend term explains most of the variation (see Table 1), equations (30) have not been corrected for serial correlation.

$$\text{(35)}\quad Log\, D/C = \underset{(12)}{8.3} + \underset{(3.2)}{0.88}\, Log \frac{Y}{L} + \underset{(3.2)}{0.53}\, Log\, N$$

$$\text{(36a)}\quad Log\, G_p = -\underset{(3.6)}{2.06} - \underset{(2.7)}{2.96}\, Log\, P - \underset{(12)}{0.057t} \qquad (1878\text{–}1889)$$

$$\text{(36b)}\quad Log\, G_p = \underset{(2.4)}{1.01} - \underset{(4.9)}{2.12}\, Log\, P + \underset{(12.4)}{0.076t} \qquad (1890\text{–}1914)$$

$$\text{(37)}\quad M^S \equiv (H_0 + G_p + XP_x - ZP_z + B_k)K; \qquad K = \frac{D/R(1 + D/C)}{D/R + D/C}$$

$$\text{(38)}\quad M^D \equiv M^S$$

In the above simultaneous system, the capital flow equation (33) was derived by assuming that the domestic interest rate moved parallel to the foreign rate[17] and cleared the bond market. Prices, on the other hand, are determined by the equilibrium condition in the money market. That is, for given supply of nominal money and demand for real balances, prices adjust in order to equate the supply and demand for nominal money. For estimation purposes, it was simpler to specify the bond and money markets and eliminate goods market by invoking Walras' law. This arbitrary choice of markets, however, should not have any effects on the results.

Three of the structural equations in the above system are reduced form equations since they are exclusively functions of exogenous variables; namely, equations (31), (34), and (35). Moreover, the break in the gold production equation makes the number of observations too few for simultaneous estimation of equation (36a). Therefore, equations (31), (34), (35), and (36a) are reproduced here from earlier ordinary least squares results. The above system of equations is not a linear one. Nevertheless, the two-stage least squares method can be used to derive consistent estimators for a simultaneous system which is non-linear in the endogenous variables but linear in the parameters.[18] As it can be seen, the simultaneous estimation of equations (32), (33), and (36b) hardly changes the value of the coefficients which gives us more confidence in their validity.

It is useful to examine the importance of individual variables in terms of their contributions to explain the variations in the dependent variables. Clearly, the size of estimated coefficients of individual regressors are no measure of importance as they are dependent on the units of measurement used. Thus, the so-called "*beta* coefficients"[19] are used here, which are derived by multiplying the coefficients of individual regressors by the ratio of their standard deviation to the standard deviation of the dependent variable, in each equation. The *beta* coefficients are standardized so that the sum of their absolute values in each question adds up to 100. These coefficients indicate roughly the relative importance of different variables in terms of their contributions to the variations in each regression. The results are summarized in Table 2, where the coefficients are listed from left to right in order of their importance.

As can be seen in this table, the rise in exports is mostly due to the rise in the value of world imports; while the rise in the *U.S.* imports is explained by the rise in domestic investment and income. Oscil-

	72	28		
Domestic gold production (G_p)	T (trend)		P	
1879–89	98.6		−1.4	
1890–1914	63		−37	

lations in the balance on capital account are to a large extent due to the changes in the domestic and foreign investments and to a lesser extent due to the changes in domestic and foreign income. The rise in the number of banks is the most important factor contributing to the rise in demand for real balances and deposit-currency ratio. This illustrates the importance of the banking development and its effects on the monetary sector. The rise in income per capita is also an important factor resulting in the rise of the demand for money and deposit-currency ratio.

VII. Synthesis of the Model

The results of the model can now be compared with those of Cagan and Friedman and Schwartz on one hand, and Williamson, Mundell, and Abramovitz on the other. In order to evaluate the above explanations of the events of the period, determinants of changes in the money supply are examined separately. Variations in the money supply are induced primarily by changes in the deposit-currency ratio and the monetary gold stock. The latter is caused by domestic gold production and the flow of international gold. The deposit-currency ratio is estimated as a function of per capita income and the number of banks, which can be considered an index of banking development. Domestic gold production is estimated as a function of the domestic price level and a trend factor to represent discoveries and technological advancements in the gold producing sector. The flow of international gold is determined by the balance on current account and the flow of capital. The latter is estimated as a function of domestic and foreign investment and income. Furthermore, nominal imports are estimated as a function of nominal investment and income, whereas nominal exports are estimated as a function of the volume of world imports.

The causes of changes in the above determinants of the money supply can be categorized into what might be called short-term and long-term. These categories are defined and analyzed separately.

A. *Short-Term Variations of the Money Supply*

Short-term changes in the money supply were induced by cyclical changes in business activity. These variations in economic activity affected the monetary gold stock by inducing variations in domestic gold production, trade balance, and international flows of capital. The effects of business cycles on the domestic production of gold and the trade balance were induced through the goods market; whereas the impact on capital flows was induced through the bond market. During the upswing of the cycle, rapid growth of output raises investment and income simultaneously in such a manner that the gap between investment and savings increases procyclically. This occurs because the rise in savings due to the rise in income during the upcycles is not enough to finance the rise in investment. The resulting gap be-

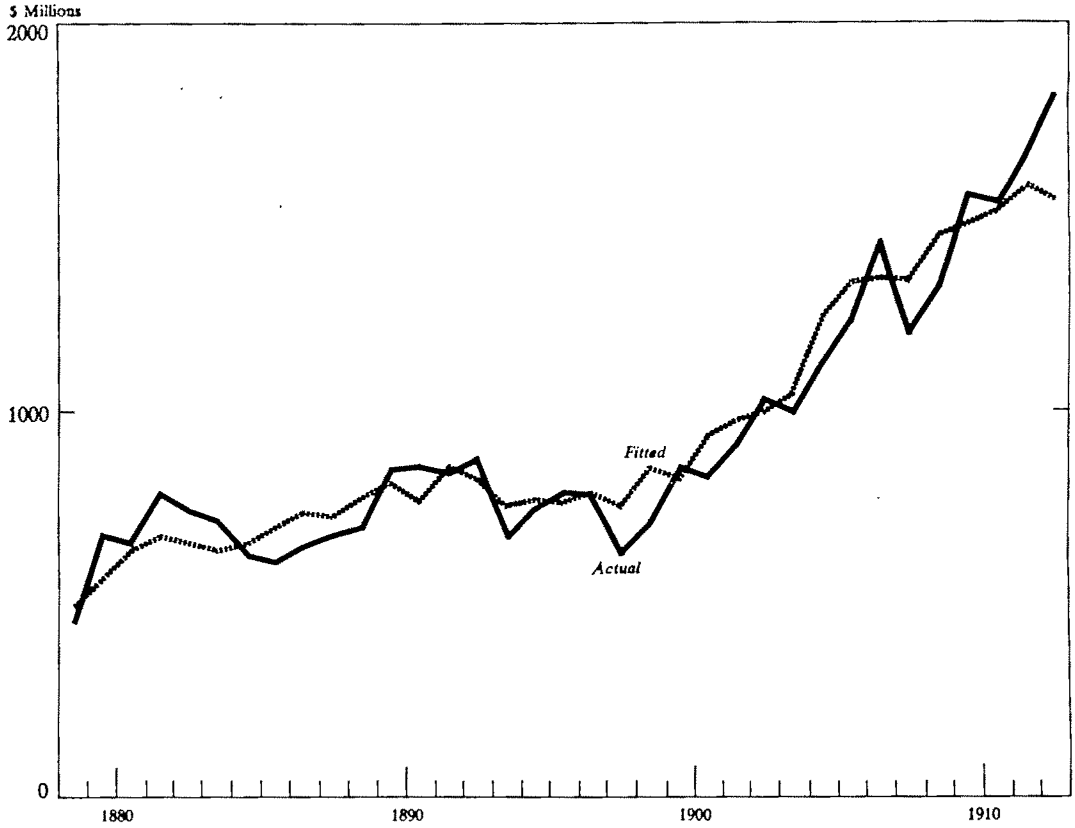

FIGURE 1. IMPORTS

tween domestic investment and savings creates an excess demand for goods and an excess supply of bonds.

The initial rise in income and investment raises imports by directly increasing the demand for consumer and investment goods (equation (32)). Moreover, during business upswings, the inflationary gap between investment and savings gives rise to an increase in domestic prices, which will ultimately eliminate the excess demand for goods. The resultant rise in prices will in turn change the terms of trade in favor of the home country, and therefore stimulate the demand for imports even further. Thus, assuming that export demand does not change (foreign demand for exports is determined exogenously), the trade balance moves anticyclically causing anticyclical variations in the monetary gold stock. Moreover, the rise in prices reduces the commodity value of gold and dampens its production (equations (36a) and (36b)), which in turn reinforces the anticyclical effects of the trade balance on the monetary gold stock.

Next, the effects of business cycles on the international capital flows are considered through the bond market. As already mentioned, the excess of domestic investment over savings during the upswings creates an excess supply of bonds forcing up the rate of interest. The rise in the interest rate eliminates the excess supply of bonds by (a) attracting capital inflows, (b) reducing the demand for money, and (c) decreasing the interest elastic portion of investment.

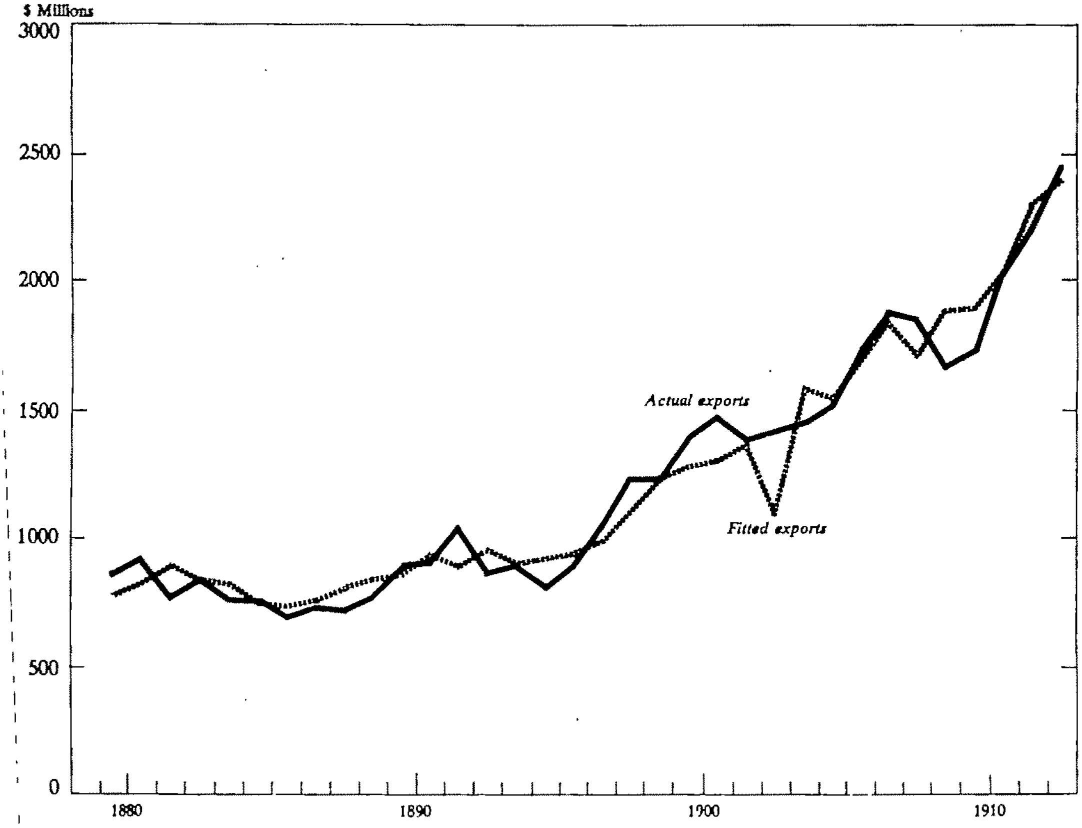

FIGURE 2. EXPORTS

The resultant effects of the shifts in income and investment on capital flows can be seen directly by considering the reduced form expression for capital inflows (equation (33)). According to this equation, an upward shift of one unit of investment, *ceteris paribus*, will induce a rise of 0.087 units in capital inflows. To the extent that income also rises during the upcycles, however, it helps to finance some of the rise in investment. Nevertheless, during the upswings the rise in savings is not enough to finance increased investments and the net effect is an inflow of capital and gold.

The above results confirm the first hypothesis set forth by Williamson and Mundell which states that allowing for cycles abroad, the capital inflows of the United States moved procyclically. The results do not confirm Williamson and Mundell's second hypothesis which claims that these procyclical movements of capital inflows dominated the anticyclical movements of imports. This second hypothesis can be easily tested by comparing the reduced form equations of capital flows (equation (33)) and demand for imports (equation (32)). Consider a simultaneous rise in investment and income such that the rise in investment exceeds the rise in savings and results in a capital inflow. First, consider the effects of the rise in investment by itself. Inasmuch as the estimated coefficient of investment in equation (32) exceeds the estimated coefficient of investment in equation (33), (.099 and .087, respectively), a rise in investment will increase capital inflows less than it

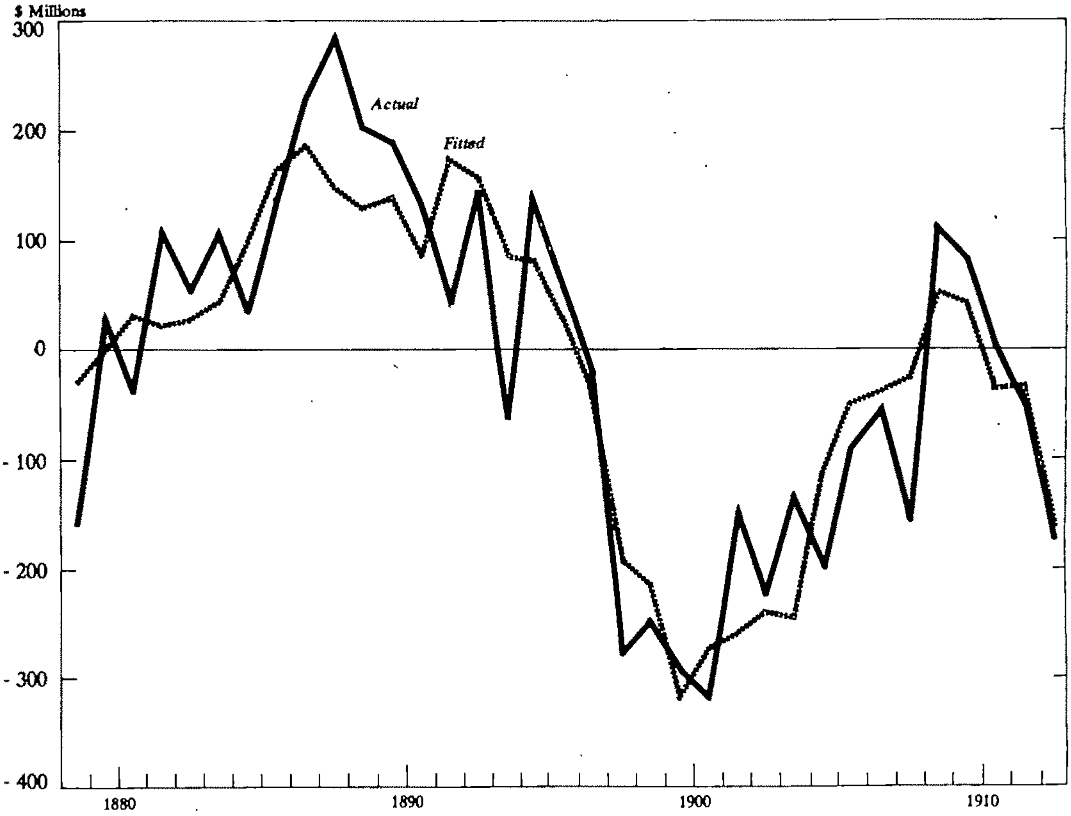

FIGURE 3. BALANCE ON CAPITAL ACCOUNT

raises imports. Thus, the resultant rise in capital inflows is more than compensated by the rise in imports, and the net effect of the rise in investment on the balance of payments is negative. Next, consider the effects of the rise in income which took place concomitantly with the rise in investment. The rise in income increases the demand for imported consumption goods and raises imports (see equation (32)). At the same time, the rise in income reduces the demand for foreign capital by raising domestic savings (see equation (33)). Consequently, the rise in income, *ceteris paribus*, will reduce the balance-of-payments surplus by reducing capital inflow and increasing imports. Therefore, the net effect of a simultaneous increase in income and investment on the balance of payments during an upcycle is negative. Thus, these empirical results indicate, contrary to Williamson and Mundell's second hypothesis, that the anticyclical movements of the trade balance dominated the procyclical movements of the balance on capital account and induced gold outflows.

So far the role of foreign factors on the balance of payments has been ignored. In fact, much of the *U.S.* capital flows in this period were caused by British business conditions. In particular, during 1897–1906, the United States was a large-scale net exporter of capital, a phenomenon which puzzled Friedman and Schwartz (see p. 142). During this period, net expenditure on British construction and railroads rose in excess of British savings. This factor, in addition to the existence of the excess of *U.S.* savings over investment, resulted in substantial capital outflows from the United States. In order to demonstrate how well the model explains the behavior of the balance of payments, the actual and fitted values of capital flows, imports, and exports are plotted in Figures 1, 2, and 3.

B. *Long-Term Variations of the Money Supply*

In the previous section it was established that the balance of payments responded to short-term variations in business activity and affected the money supply through the flow of international gold. It was argued, however, that the equilibrium of the dynamic system would imply a zero balance of payments in the long run. That is, prices and the rate of interest vary in such a way that the balance on capital account and balance of goods and services would counter each other. For empirical verification of the inverse relationship between the balance of goods and services *BGS* and the balance of capital accounts B_k, the following relationship is estimated.

$$B_k = \underset{(0.26)}{1.80} - \underset{(22)}{0.85}BGS \qquad (39)$$

$$\bar{R}^2 = .94 \qquad D.W. = 1.58$$

The above regression as well as Figure 4 illustrates that, in fact, the trade balance on goods and services and capital inflows moved opposite to each other in almost one-to-one fashion. Therefore, the net inflow of international gold was a rather small portion of the changes in the money

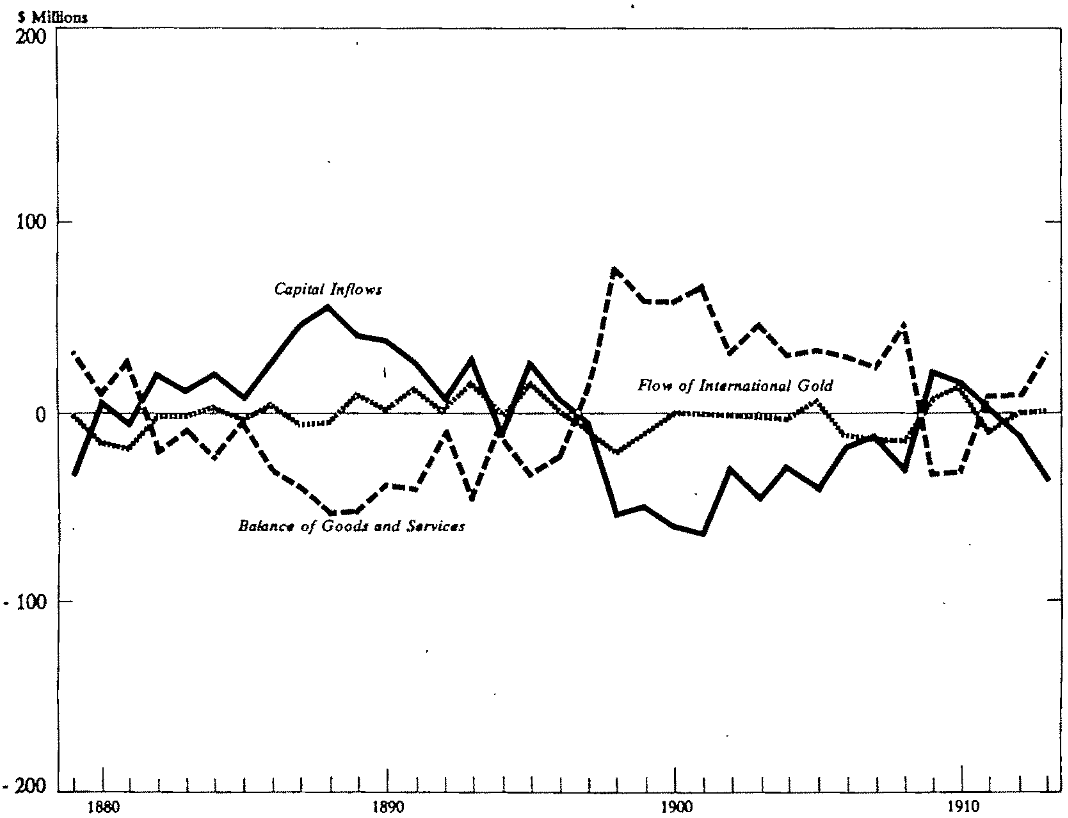

FIGURE 4

supply. Almost all of the additions to the monetary gold stock thus came from domestic production. Domestic gold production in turn was influenced by changes in domestic prices, new discoveries and technological advancements (equation (36)). The other source of long-term variations in the money supply was the deposit-currency ratio. This ratio rose over the period from a value of 2 to 7.5 due to the rise in per capita income and the number of banks (equation (35)).

We are now in a position to evaluate the Cagan and Friedman and Schwartz assumption of considering the money supply as totally exogenous. It has been shown that the rise of the money supply in the long run was caused by new discoveries of gold, improvement of gold extraction techniques, changes in domestic prices, rise of per capita income, and the increase in the number of banks. Of the above factors, the only one which is determined endogenously is the price level. Therefore, most of the long-term variations in the money supply were due to exogenous factors, a position which is consistent with Cagan and Friedman and Schwartz. As Abramovitz (1973) argues, however, it should be noted that while the rise in domestic gold production increased the money supply and satisfied the increased demand for money during this period, such increases in gold production were by no means a necessary element in the system to eliminate excess demand for money. In the absence of domestic gold production, there would have been an adjustment of *U.S.* prices; and hence of *U.S.* imports and exports, such that larger specie inflow would have compensated, at least in the short run, for smaller domestic gold production.

VIII. Conclusions

The different hypotheses set forth by Williamson, Mundell, Abramovitz, Cagan, and Friedman and Schwartz have been evaluated in the preceding sections. First, the thesis proposed by Williamson and Mundell that capital flows moved procyclically and dominated the anticyclical movements of the trade balance was tested directly. Going beyond the works of Williamson, a theory of capital flows was developed which is capable of explaining the oscillations of the balance on capital account surprisingly well. Although Williamson and Mundell were correct in proposing that capital flows moved procyclically, they were incorrect in arguing that these movements would dominate the trade balance movements.

In regard to the Cagan and Friedman and Schwartz position that the money supply was totally exogenous, the results are not as clear cut. It was established that in the short run, there were strong feedbacks from the real sector to the monetary sector through the change in prices and interest rate and their consequent effects on gold production and international gold flows. In the long run, however, the money supply was determined mostly by exogenous factors. Using a formal framework, these factors were identified as new discoveries and technological methods in gold production, rise in per capita income, and number of banks. Cagan and Friedman and Schwartz, however, give the rise in world gold production as the primary reason for the rise in the money supply. My results indicate that the rise in the money supply for this period was not entirely due to new discoveries and technological advancements in the gold producing sector. In fact, the rise in per capita income, financial developments, and changes in prices contributed significantly to the variations in money supply. Moreover, the model developed here is in agreement with Abramovitz's analysis which emphasizes the importance of balance-of-payments adjustment to clear the markets via variations in prices. It emerged that the money supply rose mostly due to the rise in domestic gold production. But this was an historical accident and in the absence of such rises in the gold production or other exogenous elements of the system, the balance of payments would react to changes in domestic prices and induce enough gold flows to eliminate excess demand for money.[20]

Investment Behavior, The Measurement of Depreciation, and Tax Policy

By Robert M. Coen*

Business income taxes are intended to tax income net of economic depreciation, that is, income net of the change in value of capital goods over the accounting period. If the effective rate of tax is to equal the statutory rate, then depreciation permitted for tax purposes must coincide with actual economic depreciation. When tax depreciation exceeds actual economic depreciation, the effective tax rate on true income is less than the statutory rate, and conversely.[1] To achieve tax equity and neutrality, the Treasury should strive to keep tax depreciation in line with economic depreciation; even if Treasury policy should seek to stimulate capital expenditures by reducing effective tax rates through liberalization of tax depreciation, a reasonable objective might be to reduce effective tax rates equally in all industries, which might require different degrees of liberalization in different industries. Efforts along these lines are greatly complicated, however, by the lack of adequate information regarding service lives and patterns of economic depreciation of capital goods in various industries.

The Treasury has relied primarily on engineering reports and special surveys of company experiences to acquire data on service lives and, to a more limited extent, on depreciation patterns; but the coverage has not been very complete, and the findings are necessarily somewhat suspect, since company representatives cannot be regarded as totally unbiased sources in such matters. Economists have attempted to measure economic depreciation principally by examining relationships between market prices of certain types of new and used assets—farm tractors, autos, and pick-up trucks, for example,[2] but the absence of active markets for many types of used industrial capital goods greatly limits opportunities for this type of analysis.

This study explores a new approach to the estimation of economic depreciation, an indirect method that attempts to infer patterns of economic depreciation from the behavior of actual capital expenditures in different industries. Section I presents a model of investment behavior that allows for alternative assumptions regarding service lives and capacity depreciation patterns. Capacity depreciation refers to losses in the productive capacity, or efficiency, of capital goods as they age. The model relates net investment to past changes in the desired, or optimal, stock of capital where the desired stock depends in a special way on the level of output, the price of output, and an implicit rental price of the capital input. Service lives and capacity depreciation patterns are shown to be central elements in the measurement of net investment and the implicit rental price of the capital input. To each service life and capacity depreciation assumption there corresponds a particular time-series for net investment and for the rental price. A range of alternative assumptions is employed in fitting the model to annual time-series data on equipment and structures expenditures in two-digit manufacturing industries. The statistical results are discussed in Section II. The service lives and capacity depreciation patterns that, among those tested, provide the best explanations of investment behavior are then translated into patterns of economic depreciation and compared with tax depreciation for each industry. This material appears in Section III. The concluding section summarizes the findings and indicates some of their important limitations.

I want to thank Raymond Scheppach, Jr., Martin Marimont, and Jack Gottsegen for their aid in obtaining various data series. John Albrecht, Barry Cohen, Edward Hair, Seung Hoon Lee, Nancy Mueller, and Jon Sonstelie provided able assistance in various stages of the research. I am deeply indebted to Seymour Fiekowsky of the Treasury who gave me constant encouragement and much helpful advice from the formative stages to final completion of this study. I have also benefitted from the comments and suggestions of Robert Eisner. The analyses and conclusions contained in this study are my own and are not necessarily shared by any of these individuals or by the Treasury Department. A more detailed version of this paper is available on request from the author.

[1] A succinct proof of this proposition has been given by Paul Samuelson.

[2] See the studies of Zvi Griliches, Phillip Cagan, Frank Wykoff, Robert Hall, and Wolfhard Ramm. Paul Taubman and Robert Rasche have measured economic depreciation of office buildings by calculating changes in the discounted value of net rents as buildings age. Allan Mendelowitz has attempted to measure economic depreciation patterns in selected industries from estimated time profiles of earnings generated by capital expenditures in a given year.

I. Service Lives, Capacity Depreciation, and the Theory of Investment

A. *Gross Investment, Net Investment, and Replacement*

Firms acquire new capital goods both to expand productive capacity (net investment) and to replace losses in the productive capacity of existing capital goods (replacement investment). The partitioning of observed gross investment into net investment and replacement can only be approximated by making some assumptions about the service life and capacity depreciation pattern of capital goods. A widely employed assumption is that the productive capacity of capital goods declines geometrically (or exponentially) with age at a rate typically, though not necessarily, equal to twice the straight-line depreciation rate. This hypothesis implies that replacement is a constant fraction of the capital stock on hand at the beginning of each period. While this approximation is a convenient one in many respects, little empirical evidence has been advanced to support it.[3] Here I shall adopt a more general approach.

Let d_{ji} be the fraction of the original productive capacity of a capital good which is lost in the ith period after its acquisition according to the jth "mortality distribution." A mortality distribution is defined by a combination of an assumed service life and an assumed pattern of capacity depreciation.[4] Replacement in

---

[3] The studies of prices of new and used farm tractors, autos, and pick-up trucks referred to in fn. 2 do lend limited support to the hypothesis of geometric decline in productive capacity. Martin Feldstein and David Foot and Robert Eisner have undertaken more direct tests of the approximation, utilizing information on replacement expenditures from the McGraw-Hill surveys. Both studies lead to a rejection of the hypothesis that replacement is a constant fraction of capital stock. Dale Jorgenson (1971) has been critical of the Feldstein-Foot and Eisner studies, arguing that the capital stock estimates which they employ are inconsistent with a varying replacement rate.

[4] I assume that losses in productive capacity depend only on the time elapsed since the acquisition date. They are independent of the calendar date at which the capital good is acquired. It should be noted, however, that d_i may relate not only to deterioration in physical characteristics of the capital good but also to obsolescence associated with improvements in efficiency of new capital goods. For example, suppose that physical deterioration in the ith period following acquisition is h_i and that technical change embodied in new capital goods is occurring at the rate g per period. Then, following the aggregation theorem of Robert Solow for the case of a Cobb-Douglas production function with constant returns to scale, the capital stock for period t in efficiency units of period t capital goods can be defined as a weighted sum of current and past capital expenditures, namely,

$$K_t = (1 - h_0)I_t + \frac{1 - h_0 - h_1}{1 + g} I_{t-1} + \frac{1 - h_0 - h_1 - h_2}{(1 + g)^2} I_{t-2} + \dots$$

The weights are the same for all t, their numerators period t corresponding to the jth mortality distribution, assuming that $d_{j0}=0$, is given by

$$R_{jt} = \sum_{i=1}^{\infty} d_{ji} I_{t-i} \tag{1}$$

where I_{t-i} is real gross investment in year $t-i$, and net investment is given by

$$N_{jt} = I_t - R_{jt} \tag{2}$$

Given a sufficiently long historical series on gross investment, net investment series can be estimated for a wide range of mortality distributions. In this study, time-series on net investment in equipment in manufacturing industries have been constructed for 40 mortality distributions—8 service life assumptions generally ranging from 8 to 22 years, in increments of 2 years, and 5 capacity depreciation patterns. Net investment series for structures have been constructed for 35 mortality distributions—7 service life assumptions ranging from 20 to 50 years, in increments of 5 years, and 5 capacity depreciation patterns.[6] The assumed depreciation patterns, which are the same for both equipment and structures, are as follows:

1) A geometric decay pattern with the rate of decay set equal to $2/n$, where n is the assumed service life. For this pattern, $d_i=\delta(1-\delta)^{i-1}$, where $\delta=2/n$, and assets continue to contribute to productive capacity beyond the assumed service life. The meaning of "service life" is somewhat ambiguous in this case; strictly speaking, the choice of n should be viewed not as specifying different service lives but different rates of geometric decay. Because capacity depreciation extends over an infinite horizon according to this pattern, I shall refer to it in brief as *GD-INF*.

2) A geometric decay pattern with the rate of decay equal to $2/n$, but truncated so that assets do not contribute to productive capacity beyond the end of the service life. This pattern shall be referred to in brief as *GD-FIN*.

3) A "sum-of-the-years-digits pattern" for which $d_i=(n+1-i)/\sum_{i=1}^{n} i$, $i=1, \ldots, n$. Like *GD-INF* and *GD-FIN*, this pattern implies more rapid capacity depreciation in the earlier years than in the later years of the service life, but the rate of decline in productive capacity is more rapid in this case. This pattern will be denoted as *SYD*.

4) A light bulb or "one-hoss shay" pattern for which no capacity depreciation occurs until the very end of the service life. For this pattern, $d_i=0$ for $i=1, \ldots, n-1$, and $d_n=1$. This pattern will be denoted as *OHS*.

5) A straight-line pattern for which $d_i=1/n$, $i=1, \ldots, n$. According to this pattern, productive capacity declines by the same amount in each year of the service life. It will be referred to in brief as *SL*.

This particular set of capacity depreciation patterns is, of course, arbitrary and by no means exhaustive, although it does represent an interesting spectrum of possi-

---

accounting for physical deterioration, their denominators for obsolescence, and they can readily be converted into a set of d_i, such that

$$1-\sum_{i=0}^{m} d_i = \frac{1-\sum_{i=1}^{m} h_i}{(1+g)^m}$$

From an empirical point of view, we specify a set of d_i to calculate a capital stock (K_t) and net investment (K_t-K_{t-1}), and we need not be concerned with the particular set of h_i and value of g which generate d_i. If embodied technical progress is not occurring, the d_i and h_i are identical; if it is occurring, we presume that our d_i capture it. In the latter case, the production function aggregated over all vintages of capital must include a trend term involving $(1+g)$; but since the trend term will not appear in the marginal productivity conditions for net worth maximization, it is immaterial.

[6] I make the simplifying assumption that capital goods are retired precisely at the end of their assumed service lives. This is unlikely in practice, but information on retirement distributions is largely nonexistent.

bilities. I must emphasize further that although the names and descriptions attached to these depreciation patterns bear similarities to the terminology of economic and tax depreciation accounting, they refer not to economic or tax depreciation, but to capacity depreciation. The relationship between capacity and economic depreciation is taken up below in Section III.

B. *The Demand for Capital*

An important innovation in recent studies of investment behavior has been the inclusion of an implicit rental price of capital as a determinant of the capital stock which firms desire to hold. The rental price measures now being used are based on the particular assumption regarding capacity depreciation discussed in the preceding section, namely, that the pattern of capacity depreciation is characterized by a decaying geometric series. Our first task in this section is to generalize the formulation of the rental price to allow for any pattern of capacity depreciation.

Suppose that firms in a given industry are considering adding one (small) unit to their capital stock.[6] We assume that the price q which they must pay for a new unit of capital, the price p which they receive for each unit of output, and the interest rate r at which they discount future revenues and costs are expected to be constant over the indefinite future. An increase in capital stock K by one unit will increase output X in each future period by $\partial X/\partial K$, the marginal product of capital. Gross revenue in each period will rise by $p(\partial X/\partial K)$, but net revenue will rise by only $p(\partial X/\partial K)-q(\partial R_{jt}/\partial K)$, where $\partial R_{jt}/\partial K$ is the increase in replacement in period t required to maintain the capital stock at its new level, assuming that the jth mortality distribution holds. Firms should add to their capital stock if the present value of the net revenues generated exceeds the price of a unit of capital. Stated algebraically, this condition is:

$$\sum_{t=1}^{\infty} [p(\partial X/\partial K) - q(\partial R_{jt}/\partial K)] \cdot (1+r)^{-t} > q \tag{3}$$

To maximize their net worth, firms should continue to add to their capital stock until (3) holds as an equality. Hence, net worth maximization requires that

$$\frac{\partial X}{\partial K} = \frac{qr\left[1 + \sum_{t=1}^{\infty} (\partial R_{jt}/\partial K)(1+r)^{-t}\right]}{p} = \frac{c_j}{p} \tag{4}$$

The expression c_j is the implicit rental price of capital corresponding to the jth mortality distribution. The rental price consists of two components. The first, rq, may be viewed as the interest per period that firms must pay on funds borrowed to finance an initial net investment of q dollars (one unit of capital). The second, $r\sum_{t=1}^{\infty} q(\partial R_{jt}/\partial K)(1+r)^{-t}$, is the present value of the cost of all future replacements (including replacements of replacements) needed to maintain one unit of capital, multiplied by the discount rate r. It represents, then, the replacement expense per period expressed as an annuity whose present value equals the present value of the cost of all future replacements.

The formula for the rental price can be simplified in the following way. Let us define F_j as the present value of the stream of capacity depreciation on a unit of capital according to the jth mortality distribution; that is,

$$F_j = \sum_{i=1}^{\infty} d_{ji}(1+r)^{-i} \tag{5}$$

---

[6] The presentation here follows my 1968 paper, except that for convenience the existence of a business income tax is ignored. In the empirical work reported on below, tax policy parameters are incorporated in the rental price.

It can be shown that

$$(6)\quad \sum_{t=1}^{\infty} (\partial R_{jt}/\partial K)(1+r)^{-t} = F_j/(1-F_j)$$

so that

$$(7)\quad c_j = qr/(1-F_j)$$

For the special case in which $d_i=\delta(1-\delta)^{i-1}$, which has been assumed in previous studies,

$$(8)\quad F = \sum_{i=1}^{\infty} \delta(1-\delta)^{i-1}(1+r)^{-i} = \delta/(r+\delta)$$

and

$$(9)\quad c = q(r+\delta)$$

which is the rental price expression commonly found in the literature.[7,8]

In this study, rental price estimates for equipment and structures in manufacturing industries are prepared for each of the mortality distributions employed in preparing the net investment series described above. Thus, for each assumed mortality distribution we have net investment and rental price estimates which are consistent with one another.

We have seen that firms should adjust their capital stock to equate the value of the marginal product of capital to its implicit rental price. We shall assume that output is produced according to the Cobb-Douglas production function

$$(10)\quad X = AL^{\alpha}(K_j^e)^{\beta_j}(K_k^s)^{\gamma_k}$$

where X=output, L=labor input, K_j^e =stock of equipment measured in accordance with the jth mortality distribution, K_k^s=stock of structures measured in accordance with the kth mortality distribution, and A, α, β_j, and γ_k are the production function parameters corresponding to the particular measures of the capital stocks. Substituting the marginal-product expressions from (10) into equation (4) and denoting the implicit rental prices of equipment and structures by c^e and c^s, respectively, we obtain the following expressions for the desired, or optimal, capital stocks:

$$(11)\quad (K_j^e)^* = \beta_j \frac{pX}{c_j^e}$$

$$(12)\quad (K_k^s)^* = \gamma_k \frac{pX}{c_k^s}$$

These stock-demand functions, which were originally derived and utilized by Jorgenson (1963), will be used in the investment relations fitted below. Considerable controversy exists over their suitability in investment analysis (see, for example, my 1969 paper), and further work is warranted to determine the sensitivity of results reported below to alternative specifications of the stock-demand functions.

---

[7] While geometric decline in productive capacity has been assumed in the rental price measures used in applied work on investment, there are to my knowledge two theoretical studies that treat other patterns of capacity depreciation and arrive at rental price expressions similar to equation (7). See the works of Kenneth Arrow and Vernon Smith.

[8] When expected prices are not constant, the implicit rental price is in general more complex and less tractable empirically than equation (7). In the special case of geometric decay, the rental price for period t becomes $q_t(r+\delta)-(1-\delta)(q_{t+1}-q_t)$. Presuming that q_t is known to firms, all that we would need to estimate is their expectation of the price of capital goods in t+1, q_{t+1}. However, for other patterns of capacity depreciation, the rental price for period t will depend on the expected prices of capital goods at *every* future date. We could make the simplifying assumptions that 1) firms expect capital goods prices and all other prices to rise at a constant rate over the indefinite future, and 2) they expect the nominal rate of interest each period to reflect fully the rate of inflation, with the real rate of interest remaining constant. If this were so, then equation (7) holds, provided that r is the real rate of interest and F_j is calculated using the real rate of interest. In my empirical implementation of (7), I assume that r is constant over time and that it measures the real marginal rate of return on capital desired by firms. This is consistent either with the assumption that expected prices are constant and equal to current prices or with the set of assumptions stated in the middle of this paragraph.

C. *Investment Demand*

Net investment measures the flow of current new additions to capital stock, and it seems reasonable to relate net investment to current and past changes in the desired capital stock. The lag distribution which I shall assume is the relatively flexible form employed by Hall and Jorgenson in their study of annual investment for total manufacturing. The first two terms of the lag distribution are freely estimated, and the remaining terms are presumed to decline at a geometric rate. The equations for net investment (one for equipment, one for structures) take the form:

$$\begin{aligned}(13)\qquad N_{jt} &= \omega_{1j}(K^*_{jt} - K^*_{j,t-1}) \\ &\quad + \omega_{2j}(K^*_{j,t-1} - K^*_{j,t-2}) \\ &\quad + \lambda_j N_{j,t-1} + u_{jt}\end{aligned}$$

where ω_{1j}, ω_{2j}, and λ_j are the parameters of the lag distribution, and u_{jt} is a random error, everything holding for the jth mortality distribution. For example, if we substitute the expression for the desired stock of equipment into equation (13), we have

$$\begin{aligned}(14)\qquad N^e_{jt} &= b_1\left(\frac{p_tX_t}{c^e_{jt}} - \frac{p_{t-1}X_{t-1}}{c^e_{j,t-1}}\right) \\ &\quad + b_2\left(\frac{p_{t-1}X_{t-1}}{c^e_{j,t-1}} - \frac{p_{t-2}X_{t-2}}{c^e_{j,t-2}}\right) \\ &\quad + b_3N^e_{j,t-1} + u_{jt}\end{aligned}$$

where b_1, b_2, and b_3 are the regression coefficients to be estimated. We see that $b_1=\omega_{1j}\beta_j$, $b_2=\omega_{2j}\beta_j$, and $b_3=\lambda_j$. Employing the proposition that the terms of the lag distribution must sum to unity, we can identify the parameters β_j, ω_{1j}, and ω_{2j}, from estimates of the b coefficients.

Replacement investment is assumed to be equal each year to replacement requirements calculated according to the jth mortality distribution, R_{jt}. Thus, if our net investment relation gives a prediction $\hat{N}_{jt}$ for net investment in year t, according to the jth mortality distribution, then our prediction of gross investment identified with the jth mortality distribution is

$$(15)\qquad \hat{I}_{jt} = \hat{N}_{jt} + R_{jt}$$

Since $I_t = N_{jt} + R_{jt}$, the error in our prediction of gross investment in year t when we assume the jth mortality distribution is

$$(16)\qquad I_t - \hat{I}_{jt} = N_{jt} - \hat{N}_{jt}$$

that is, the prediction error for gross investment is equal to the prediction error for net investment. Thus, while we are actually interested in comparing the ability of alternative mortality distributions to explain gross investment, we are able to make the comparisons by examining the predictive accuracy of the fitted net investment relations.

Although the form of the lag distribution assumed here is relatively flexible, it does have limitations in that it imposes the same lagged response of net investment to changes in all the variables which determine the desired stock of capital. Also, we have assumed that factor proportions can readily be changed both before and after capital goods are put in place—the so-called putty-putty situation. In a putty-clay model, the mortality distribution of capital goods is a crucial determinant of the distributed lag on price changes, since new factor proportions associated with price changes (demand constant) can be incorporated only in replacement of existing capacity.

II. Investment Relations for Equipment and Structures in Manufacturing Industries

A. *The Data*

My empirical analysis of investment behavior covers twenty-one manufacturing industries listed in the Standard Industrial Classification (*SIC*) code. The annual gross investment data used to compute post-World War II measures of net investment and replacement for each mortality distribution were taken from a study prepared by Jack Faucett Associates, giving current and constant (1958) dollar gross investment in equipment for 1921–66 and in structures for 1890–1966. Faucett used the Commerce Department's structures deflator (constant cost 2) for total manufacturing in obtaining constant dollar estimates of structures investment; the same deflator was used in all manufacturing industries. The equipment deflators vary from industry to industry, however, the deflator for each industry being a weighted average of the Commerce Department's deflators for different types of equipment, with the weights reflecting the industry's use of each type of equipment.

Estimates of the implicit rental prices of equipment and structures are based on equation (7) above, except that adjustments are made to account for influences of tax policy. The formula used is:

$$c_j = \frac{q r}{1 - F_j} \cdot \frac{1 - s - \tau(1 - ms)B}{1 - \tau} \tag{17}$$

where s = the rate of investment tax credit, τ = the tax rate on business income, m = the proportion of the investment credit that must be deducted from the depreciable base of assets on which the credit is claimed, and B = the present value of the stream of depreciation for tax purposes stemming from one dollar of current investment. The second fraction on the right-hand side of (17) is the tax adjustment factor, which I have derived in previous studies (1968, 1971). This factor is the same for all mortality distributions. Service lives and depreciation patterns permitted for tax purposes determine B, whereas the mortality distribution determines F. As we experiment with different mortality distributions, we change F but not B.

The Faucett deflators for capital expenditures are used as estimates of the prices of new capital goods, and the discount rate is set at 10 percent per annum, the same for all years and industries. The rate of the investment credit for equipment (there has been no credit for structures investment) was set at 3.5 percent for 1962, 7 percent for 1963–65, and 5.25 percent for 1966. The 1962 and 1966 rates reflect the fact that the credit was available only for parts of these years. The proportion of the investment credit that must be deducted from the depreciable base is unity in 1962–63 and zero thereafter, reflecting repeal of the Long Amendment in the Revenue Act of 1964. The tax rate is set equal to the maximum statutory corporate income tax rate.

The value of B is a weighted average of present values of tax depreciation for three write-off methods: straight-line, double-rate declining-balance (with a switch to straight-line after the midpoint of the asset's life), and sum-of-the-years-digits. For 1947–53, straight-line is given a weight of unity, the others zero. Thereafter, the weights are .293, .354, and .353, respectively, for equipment and .349, .302, and .349 for structures, reflecting the liberalization of depreciation methods which occurred in 1954. These weights are based on information gathered by the Treasury in the 1950's as reported by Norman Ture. The same weights are used for all industries, since more detailed information is not available.

The service life of structures for tax purposes is set at 23 years throughout the 1947–66 period, the same for all industries. This estimate is again based on Ture's examination of Treasury survey data. More detailed information was available for equipment, including average and median service lives for tax purposes at roughly the two-digit *SIC* level for samples of firms in the late 1950's. From these data, judgmental estimates were made for the industries included in this study, and these estimated lives were assumed to hold for the period 1947–61. The guideline lives published by the Treasury in 1962 were assumed to hold for the period 1962–66. The guideline classes do not correspond exactly to the two-digit *SIC* breakdown, so some subjective adjustments were necessary. The final estimates of equipment lives for tax purposes by industry are given below in Table 3 of Section III. The third column of Table 3 gives service life estimates representing the lower bounds of lives permitted under the *Asset Depreciation Range* (*ADR*) *System*, which took effect in 1971. They are not used in estimating the present investment relations, but will be used in Section III where comparisons are made between economic and tax depreciation. Finally, the output measure for each industry is gross product originating.

B. *The Net Investment Regressions*

Net investment relations of the form of equation (14) were fitted to annual equipment and structures expenditures for the period 1949–66.[9] The following procedure was used in selecting the "best" mortality distribution for each type of asset in each industry. The first step involved ranking the regressions for the various mortality distributions in terms of their ability to explain gross investment over the sample period. As we saw above, errors in predicting gross investment for a given mortality distribution are equal to those in predicting net investment for that mortality distribution. Thus, the goodness of fit statistic from the regressions that is appropriate to ranking them is the standard error of estimate. If the mortality distribution yielding the lowest standard error of estimate implied reasonable parameters for the lag distribution and the production function, then it was selected as the best mortality distribution, i.e., the mortality distribution indicated by the behavior of capital expenditures. If implausible parameters for the lag distribution and/or the production function were implied by the best fitting mortality distribution, the search was continued until the best fitting mortality distribution which also had reasonable implications was discovered.

Two criteria were employed in judging the reasonableness of the implied parameters of the lag distribution and the production function. First, the estimate of λ was required to be less than unity. If λ were greater than one, the adjustment of capital stock to its desired level would be unstable. Second, estimates of the elasticities of the stocks of equipment and structures in the production function (β for equipment and γ for structures) were required to be positive and less than unity. Elasticities greater than unity imply increasing marginal products, a violation of the second-order conditions for net worth maximization.

An example will help to illustrate the procedures followed. Consider *SIC* 22, textile mill products, for which the standard errors of estimate are summarized in Table 1. The best fitting equations for equipment were, in descending order, those corresponding to *SL* with a 14-year service life and *SL* with a 12-year service life. The first of these implied an estimate of β of 1.595, while the second implied an estimate of β of .583; hence, the first was rejected and the second selected as best. For structures, there are many equations yielding

---

[9] In most instances, the residuals showed first-order autocorrelation, and the regressions were rerun using transformations of the original variables of the form $y_t - \hat{\rho} y_{t-1}$, where $\hat{\rho}$ is the autocorrelation coefficient computed from the estimated residuals of the initial regression. Since one observation is lost when this transformation is performed, the adjusted equations are fitted to observations for 1950–66, rather than 1949–66. A complete tabulation of the regressions is available on request.

50	13.12	14.77	14.71	24.01	18.24

better fits than *OHS*-30, which was finally selected, but each one gave an estimate of λ greater than unity.

Examination of Table 1 reveals general characteristics of the results which are worth noting. First, there is considerable variation in the standard errors of estimate among mortality distributions. The empirical model of investment behavior employed here does appear to be sensitive to specification of the mortality distribution and does discriminate among the alternatives, more so in some industries than in others. Second, the standard errors of estimate for a given capacity depreciation pattern often change in a capricious manner as the service life is varied. Changes in the service life can lead to sizable, abrupt changes in the estimates of net investment, particularly when the capacity depreciation pattern is not very smooth. The service life determines the length of the historical period which influences estimates of net investment in the postwar era, and even small changes in the service life may lead to the inclusion or exclusion of rather unusual historical experiences.

Table 2 lists the final mortality distributions selected for each industry and gives the lag distribution and production function parameters implied by the regressions corresponding to those mortality distributions. An interesting feature of Table 2 is the appearance of only one case in which the *GD-INF* capacity depreciation pattern —the one typically used in recent studies of investment behavior—yielded the best results. However, capacity depreciation patterns which imply losses in productive capacity over the service life are predominant for equipment. A very striking finding is that the *OHS* depreciation pattern yields the best results for structures in eleven industries.

In general, the regressions for each industry must be carefully reviewed to determine their reliability. The particular model of investment behavior employed here does not perform equally well in each industry and for each type of asset. More-

over, in many instances a short service life combined with a slow capacity depreciation pattern gave results that were not very different from those obtained for a longer service life combined with a faster capacity depreciation pattern. Perhaps a more discerning test in these cases would be a comparison of postsample predictions from the competing alternatives, but I have not yet attempted this. While the analyses in Section III will treat the mortality distributions in Table 2 as "point estimates," they should more often be viewed as the best (marginally superior) estimates among a set of perhaps three or four candidates suggested by the regressions.[10]

III. Comparisons of Tax Depreciation Practices with Depreciation Indicated by Investment Behavior

A. *Service Lives for Tax Purposes Compared with Estimated Service Lives*

The mortality distributions indicated by investment behavior can be used in a variety of ways in examining depreciation practices for tax purposes. One interesting comparison is that between service lives employed for tax purposes and those revealed by actual capital expenditures. Table 3 provides such comparisons. Equipment service lives for tax purposes prevailing before 1962 were generally above those indicated by investment behavior, in many cases by substantial margins. The 1962 guidelines generally brought tax lives into closer agreement with those revealed by investment behavior; for 10 of the 21 industries, guideline lives were within two years of revealed service lives, compared with only 3 of 21 in the preguideline era. The *ADR* lives currently permitted are below revealed service lives in 15 of the 21 industries, although they are within 2 years of revealed service lives in 10 industries. Only 2 industries, primary metals and motor vehicles, appear to have *ADR* lives substantially above revealed service lives. In both instances, however, Table 3 is very likely misleading. The *ADR* life of 10 years for motor vehicles is for general machinery and equipment. The Treasury has permitted auto producers to depreciate special tools, dies, and jigs over a period of about 3 years, since these items are typically replaced with each major model change. Since they account for a significant portion of equipment expenditures (over 50 percent according to Treasury estimates), the actual tax life in this industry is certainly less than 10 years. The problem in primary metals is the classification of blast furnaces. For tax purposes they are depreciated as equipment, but they are classified as structures in the investment series used here. Hence, the revealed service life in Table 3 probably underestimates the life of those assets actually depreciated as equipment.

According to the weighted-average equipment lives at the bottom of the table, 1) the preguideline average tax life for manufacturing equipment exceeded the revealed service life by 3.6 years, or about 28 percent, 2) the guidelines equalized the average tax life and the revealed service life, and 3) *ADR* reduced the average tax life to a level about 19 percent below the revealed service life. While these averages provide additional perspectives on the findings, they can and do, of course, conceal serious inequities or advantages ap-

---

[10] Tests of the significance of differences in the variances of residuals obtained for alternative mortality distributions might seem appealing, but they would be quite complex and, I believe, suspect. Given the research design, there is good reason to believe that residuals for any two mortality distributions will be highly correlated, and in fact they generally are. Hence, the conventional F-test for equality of two variances, which is founded on the assumption that the variables are independently distributed, is not appropriate. Also experimentation with such a large number of mortality distributions has certainly exhausted the degrees of freedom in this sample.

parently experienced by particular industries.

Table 3 indicates that revealed lives for structures are generally much longer than the 23-year average tax life in manufacturing. Indeed, in 11 industries revealed lives range from about 74 percent to 117 percent above tax lives. The weighted averages at the bottom of the table show a tax life for manufacturing structures that is 12.4 years, or about 35 percent, below the revealed life. While the long lives indicated by investment behavior in several industries are far out of line with the average tax life in manufacturing, they are not out of line with the service lives of 45 to 50 years set forth in the Treasury's *Bulletin F* and in the 1962 *Guidelines*. Indeed, in light of the Treasury's prescribed lives, the observed average tax life of 23 years seems surprisingly low.

B. *Comparisons of Estimated Economic Depreciation and Tax Depreciation*

Even though an industry may be using a tax life that corresponds to its retirement practices, it may be writing off assets over the tax life at a rate that exceeds or falls short of actual economic depreciation. By comparing the present values of the streams of tax and economic depreciation on one dollar of capital expenditures, we can gain additional insight into the impact of depreciation policy. To do this, we must first see how our mortality distributions which relate to capacity depreciation can be translated into patterns of economic depreciation.

If prices are expected to remain constant or to change at a constant rate with r being the real rate of interest, then the value of an asset at the beginning of year t of its service life V_t should equal the present value of the stream of productive capacity from year t to the end of the service life (year n). For example, the *OHS* capacity depreciation pattern specifies that productive capacity is the same in each year of the service life; assume that it is unity. Then

$$V_t = \sum_{i=0}^{n-t} (1+r)^{-i} \tag{18}$$
$$= (1+r)[1-(1+r)^{t-n-1}]/r$$

Economic depreciation in year t is the loss of value during the year, or $V_t - V_{t+1}$; and $v_t = (V_t - V_{t+1})/V_1$ measures the loss in value relative to the value when new. Hence, the v_t describe the pattern of economic depreciation on an asset whose initial value is one dollar, and $\sum_{t=1}^{n} v_t(1+r)^{-t}$ is the present value of the stream of economic depreciation. For reasonable discount rates, the *OHS* pattern implies that economic depreciation occurs at a slower pace in the early years of an asset's life than in the later years, but the other patterns imply the reverse. And in the case of *GD-INF*, we have the special result that economic and capacity depreciation are identical in each year.

Table 4 presents ratios of present values of tax to estimated economic depreciation. Ratios for equipment are shown for four eras of depreciation policy. Tax allowances in the preguideline, pre-acceleration era (1947–53) were well below economic de-

preciation in all but 4 industries. While service lives for tax purposes in 2 of these industries exceeded the service lives indicated by investment behavior, even the straight-line write-off method gave rise to tax depreciation that was considerably more rapid than that implied by the capacity depreciation patterns evidenced by equipment purchases in these industries. For many industries in which the pre-guideline lives were roughly in accord with revealed service lives, the present value of tax depreciation fell short of economic depreciation by 15 to 20 percent, because the straight-line write-off method was too slow relative to the implied patterns of economic depreciation.

The adoption of accelerated write-off methods in the second era generally increased the present values of tax depreciation relative to economic depreciation by about 10 percentage points. This was sufficient to add 3 industries to the list of those for which the present value of tax depreciation roughly equalled or exceeded that of economic depreciation. The guideline lives identified with the third era further increased the present values of tax depreciation, though not as uniformly as did the accelerated write-off methods. Under the guidelines, 12 of the 21 industries were permitted tax write-offs that roughly coincided with or exceeded economic depreciation.

The *ADR* system instituted in 1971 increased the present values of tax depreciation by about 6 to 10 percentage points relative to economic depreciation. Since *ADR* involved a 20 percent reduction in tax lives across the board, the largest benefits were conferred on industries whose pre-*ADR* tax lives were longest. If these were the industries experiencing the least favorable treatment prior to *ADR*, then *ADR* would have moderated existing inequities; but close inspection of Tables 3 and 4 reveals that this was not entirely the case. The weighted averages given in the last row of the table indicate that under the guidelines the present value of tax depreciation exceeded economic depreciation of all manufacturing equipment by 2.8 percent; under *ADR*, this figure rose to 10.8 percent.

Service lives of structures for tax purposes have not been altered since 1947 (at least not by statute or administrative ruling), so that only the pre- and post-acceleration eras need be distinguished. The picture revealed by Table 4 is a very mixed one indeed. Since service lives indicated by investment behavior are in many instances a decade or two longer than the 23-year average tax life, it is not unusual for the present values of tax depreciation to exceed economic depreciation by substantial amounts. This tendency is further strengthened by the relatively slow capacity depreciation of structures evidenced by investment behavior in many industries. Even if tax lives permitted in many of these industries were increased to the 40–50-year lives indicated by investment behavior, tax write-offs would still be excessive due to the use of uniform or accelerated depreciation for tax purposes, when economic depreciation occurs at the decelerated pace associated with *OHS* capacity depreciation.

IV. Conclusions

The new approach to determination of service lives and capacity depreciation patterns of industrial assets pursued in this study appears to be a promising one. The present findings pertaining to manufacturing industries may be summarized as follows:

1) Tax service lives for equipment prescribed by the Treasury in 1962 were on the average in line with service lives revealed by investment behavior; consequently, the lower-bound *ADR* lives currently permitted are roughly 20 percent

shorter than revealed service lives. Revealed service lives of structures are substantially longer than those used for tax purposes in the postwar period, although they are on the average somewhat shorter than the lives prescribed by the Treasury in *Bulletin F* and the 1962 *Guidelines.*

2) Geometric decay of productive capacity—a commonly employed assumption in recent studies of investment behavior—does not appear to underlie actual capital spending decisions. Equipment generally evidences losses in productive capacity as it ages, though not necessarily at a geometric rate, but structures in the majority of industries suffer no loss in productive capacity over their service lives (they resemble one-hoss shays).

3) The derived estimates of economic depreciation patterns indicate that write-offs permitted under current tax regulations are on the whole generous, particularly for structures. While equipment write-offs under the 1962 *Guidelines* were on the average approximately in line with estimated economic depreciation, the *ADR* system instituted in 1971 allows excessively rapid tax depreciation.

It should be recalled that these are the *general* findings; they do not necessarily hold for each of the 21 industries studied. Of course, the present results must be viewed cautiously, since they are based on a particular, highly constrained model of investment behavior and on statistical criteria that do not include evaluations of the postsample predictive performance of alternative mortality distributions. There is some danger that the mortality distributions selected here just happen to yield good results over the period of fit, and in some instances the sample period fits were nearly identical for several mortality distributions. Also, it has been assumed throughout this work that actual service lives were constant over the period studied—not just the sample period for the investment regressions, but the entire historical period over which gross investment outlays were cumulated to obtain postwar estimates of net investment and replacement. Service lives are, however, decision variables for firms, and their optimal values may be influenced by tax depreciation policy, income tax rates, and investment credits, among other things.[11] This complex issue merits careful attention, but the theory of optimal service lives has not yet been shaped in an empirically operational form for studying investment behavior.

Wealth Neutrality and Local Choice in Public Education

By Martin S. Feldstein*

A series of recent judicial decisions has focused public attention on the issue of local choice in the provision of public education. In *Serrano vs. Priest*, *Rodriguez vs. San Antonio* (1971), and similar cases in other states, the lower courts confirmed that education is a responsibility of the state government and held that local expenditures on education may not be a function of the taxable wealth of the local community.[1] Although the United States Supreme Court has overturned these decisions in the appeal of *Rodriguez vs. San Antonio* (1973), the pressure to change the current system remains strong. The Supreme Court majority indicated that its decision reflected the limits of the federal constitutional authority and was not an approval of the status quo in educational finance. Litigation is now likely to shift to challenging the current methods as unconstitutional under state constitutions which, unlike the federal constitution, do deal specifically with education.[2] Moreover, fundamental changes in the financing of local education may not require further pressure from the courts; state legislatures may seek to neutralize the effects of local wealth differences even if the current systems are not held to be unconstitutional.

These judicial decisions and the ensuing legislative proposals run counter to the general economic view of local government finance. The basic presumption of economic analysis is that, because local governments can select different levels of service and because individuals can choose their area of residence, decentralized finance by local governments allows the provision of public services to reflect the variety of individual preferences for public services.[3] Although the level of local spending may be nonoptimal because of intercommunity externalities and because of the method of local budget determination, fiscal decentralization still remains the only alternative to the insuperable problem of determining the optimal level of expenditure on a public service provided by a central government. In effect, autonomous decentralized financing of education provides a quasi market in which households can exercise their diverse preferences by their location decisions.

This paper considers the problem of

I am grateful to Charles Clotfelter for assistance with the statistical analysis, to Stephen Weiss for providing unpublished data on school expenditures, and to the Ford Foundation and National Science Foundation for financial support. I have benefited from discussions of an earlier version in seminars at Harvard, M.I.T., and Berkeley, and from comments by Noel Edelson, Eric Toder, and David Stern. An earlier and more complete discussion of this study was distributed as Harvard Institute of Economic Research paper no. 293, May 1973 (revised July 1973).

[1] In *Serrano vs. Priest*, the landmark case in this area, the plaintiff and the courts were very much influenced by the line of argument and suggested remedies developed in John Coons et al. For a further discussion of the legal precedents, see Arthur Wise.

[2] Almost immediately after the United States Supreme Court decision in *Rodriguez vs. San Antonio*, the New Jersey Supreme Court held that the current system of local finance violated the New Jersey state constitution. See Wise for a summary of the provisions of other state constitutions.

[3] Charles Tiebout presented a formal analysis of the full efficiency of local government provision of public services under quite special conditions. See Wallace Oates and James Buchanan and Charles Goetz for a further discussion of these issues.

financing local public education in a way that partially or completely neutralizes the effects of local wealth differences without sacrificing the opportunity for local choice. The issues dealt with are likely to be important not only in educational finance but also in other areas of intergovernmental fiscal relations. Moreover, although the entire discussion in this paper is in terms of intergovernmental grants, the same principles can be applied in the design of subsidies to individuals. I return to this in the concluding section.

I. Achieving Wealth Neutrality

In the past few years, there has been increasing attention to the task of combining equity and efficiency in the solution of public sector problems. Specific studies have dealt with optimal taxation, public sector pricing, and the evaluation of public expenditure decisions. In these studies, the consumption of goods and leisure affect social welfare through individualistic utility functions, i.e., the preferences of each individual are assumed to "count." Distributional considerations enter because of the assumed concavity of the individual utility function or of the social welfare function.

A quite different type of distributional concern, which might be called "categorical equity," has been prominent in public debate and legal analysis. The principle of categorical equity singles out particular categories of services such as education and health care which are deemed to be "fundamental interests" and asserts that individuals' consumption of these services should not be allowed to differ substantially or, alternatively, that such differences should not bear a strong relation to the individuals' ability to pay.[4] The current study is limited to the second form of categorical equity, which I shall refer to as "wealth neutrality."

The general problems of achieving wealth neutrality in a decentralized system and of balancing categorical equity and other aspects of economic welfare are well illustrated by the issues of educational finance. In the basic *Serrano vs. Priest* decision, the California Supreme Court asserted the principle of wealth neutrality by stating that the California system of education is unconstitutional because "it makes the quality of a child's education a function of the wealth of his parents and neighbors" (p. 504). The court also emphasized that its decision did not require the state to spend the same amount per pupil in all districts and did not imply that the use of the local property tax is per se unconstitutional. The court did not propose any specific remedies but ordered the state to devise a new method of educational finance.

Two alternative methods are now being considered by state authorities and educational finance specialists: full state assumption of all school finance and the so-called "power equalizing" formula for state aid to local communities (see John Coons, William Clune, and Stephen Sugarman). The full state assumption of school finance would in fact equalize per pupil spending in all districts and would completely eliminate local financial decision making in education.[5] Since the purpose of the current paper is to consider ways of achieving wealth-neutrality without sacrificing local choice, the proposal for full state assumption of educational finance will not be considered. The power equalizing formula will be examined below and criticized for its almost certain failure to achieve its goal of complete wealth neutrality. An alternative "wealth neutralizing matching grant" will be described which has the virtue of preserving local choice while permitting state governments both to achieve any desired degree of wealth neutrality and to provide any desired stimulation to the average level of school spending.

---

[4] Note that the principle of categorical equity is therefore quite different from the traditional notions of vertical equity and horizontal equity (see Richard Musgrave), in which all goods and services are treated alike. Although Musgrave's concept of "merit wants" does single out particular categories of goods, the concern is not with the *distribution* of consumption of these goods but rather with encouraging *additional* consumption of goods that are deemed to be more "meritorious" than individual consumption decisions recognize. While a merit good may also be the subject of categorical equity, it is possible to want to increase the equality of consumption without increasing and possibly while decreasing the average level. In contrast, Kenneth Arrow's recent paper deals with a utilitarian form of categorical equity.

[5] Some proponents of the state assumption of educational finance advocate equalizing local spending per

It is useful to restate the *Serrano vs. Priest* mandate that educational spending not be a function of local wealth as the more precise rule that the elasticity of local educational spending per pupil with respect to the value of local taxable property per pupil be zero. The court's decision in the case of *Serrano vs. Priest* makes it clear that the "quality" of education is to be interpreted as expenditure per pupil and that local "wealth" is to be interpreted as the fair market value of taxable property. Alternative (and probably more appropriate) measures of household wealth could be used in the same way. Similarly, expenditure per pupil could be modified to reflect local differences in input prices or student abilities.

More generally, the wealth elasticity of school spending can serve as a measure of the degree of wealth neutrality or nonneutrality that has been achieved. The constant elasticity log-linear relation between expenditure per pupil in community i (E_i) and wealth per pupil (W_i) may be written:

$$(1) \qquad \ln E_i = \alpha_0 + \alpha_1 \ln W_i + u_i$$

where α_0 is a constant and u_i is a residual that is uncorrelated with $\ln W_i$. The parameter α_1 measures wealth neutrality; complete wealth neutrality requires $\alpha_1 = 0$. Note that while complete equality would imply that the variance of u_i is also zero, this is not required for complete wealth neutrality.

Consider now a more general constant elasticity equation describing the relation of expenditure to wealth, to the net price that the community pays per dollar of educational expenditure P_i, and to other variables X_{ji} that need not be defined at this point:

$$(2) \qquad \ln E_i = \beta_0 + \beta_1 \ln W_i + \beta_2 \ln P_i + \sum_{j=3}^{K} \beta_j \ln X_{ji} + \epsilon_i$$

The price variable P_i reflects the extent and form of grants from the state government to the locality; if m_i is the amount of additional state aid received by the town when it spends an additional dollar on education (i.e., the effective matching rate), the net price is defined by $P_i = 1 - m_i$. Equation (2) implies that the state government can neutralize the effect of intercommunity wealth differences by using a matching grant formula in which the rate of matching varies inversely with local wealth. More specifically, the wealth neutrality coefficient (α_1 of equation (1)) is related to the behavioral parameters of equation (2) by:

$$(3) \qquad \alpha_1 = \beta_1 + \beta_2 \cdot \gamma_{pw} + \sum_{j=3}^{K} \beta_j \gamma_{x_j w}$$

where γ_{pw} is the constant elasticity of P with respect to W and $\gamma_{x_j w}$ is the elasticity of X_j with respect to W. This relation holds both for the "true" population parameters (α, β, and γ) and also for the least

---

"equivalent pupil" and would allow local school districts to supplement state funds by up to 10 percent. Full state assumption has been supported by the Advisory Commission on Intergovernmental Relations, the President's Commission on School Finance, the New York State Commission, and others.

squares estimates that would be used to make the analysis operational.[6]

It is convenient to combine the partial wealth elasticity (β_1) and the other terms that do not relate to price into a single "adjusted" wealth elasticity ($\beta_w = \beta_1 + \sum_j \beta_j \gamma_{x_j w}$) and to relabel the partial price elasticity ($\beta_p = \beta_2$). Equation (3) may now be rewritten:

$$\alpha_1 = \beta_w + \beta_p \gamma_{pw} \tag{4}$$

This is the key equation in analyzing the wealth neutralizing effects of government grants. Since β_w and β_p are behavioral parameters of the educational system, equation (4) implies that the state government can achieve any desired degree of wealth neutrality by a system of matching grants that has the corresponding elasticity of price with respect to wealth (γ_{pw}).

More specifically, the price formula:

$$p_i = kW_i^{\gamma_{pw}} \tag{5}$$

will achieve the wealth neutrality implied by equation (4). Complete wealth neutrality ($\alpha_1 = 0$) is obtained simply by setting $\gamma_{pw} = -\beta_w/\beta_p$. Note that the parameter k of the price formula has the effect of increasing (or decreasing) the level of spending in all towns by the factor k^{β_p}. The state can therefore achieve any desired stimulation of local spending as well as any desired degree of wealth neutrality. Alternatively, the state can achieve the desired wealth neutrality subject to a constraint on the total state budget. By analogy with Jan Tinbergen's analysis of macro-economic policy, the state can achieve any two "targets" (the degree of wealth neutrality and the average level of E or the budget constraint) because it chooses two policy values (k and γ_{pw}).

The wealth neutrality relation of equation (4) shows the inappropriateness of the "district power equalizing" (*DPE*) approach that has been so widely advocated as a method of achieving complete wealth neutrality. Coons et al. use the term district power equalizing to describe a state's system of educational finance if any two school districts that levy the same rate of tax on local wealth have the same level of educational spending. In a sense, *DPE* gives each town the same tax base per pupil; district "power" equalizing is really district "tax base" equalizing. The basic *DPE* formula is equivalent to a percentage equalization grant; i.e., in the current notation the matching rate is $m_i = 1 - kW_i$. The price is thus simply proportional to wealth: $P_i = kW_i$ and therefore $\gamma_{pw} = 1$. It is clear from equation (4) that *DPE* would only be completely wealth neutralizing ($\alpha_1 = 0$) in the very special case in which the absolute wealth and price elasticities were equal.

More generally, with *DPE*, $\alpha_1 = \beta_w + \beta_p$. If the adjusted wealth elasticity exceeds the price elasticity ($\beta_w > -\beta_p$), *DPE* would still leave a positive elasticity of educational expenditure with respect to wealth. Conversely, if the price elasticity exceeds the wealth elasticity, *DPE* would invert the usual wealth-spending relation. The advocates of *DPE* essentially ignore the fact that it may leave a substantial relation (positive or negative) between wealth and school spending because they misinterpret what *DPE* actually does. It is argued that *DPE* " . . . eliminates wealth as a factor determining the offering" (Coons et al., p. 104) of education because they regard *DPE* as changing the wealth of the town when it actually changes the town's net price. A related confusion is treating the local tax *rate* as a price or a measure of "effort." Although *DPE* is sometimes interpreted as equalizing the "price" per dollar of educational services (where price is the rate of tax on local wealth), the relevant price is the local revenue per dollar of educational services purchased and not the rate of tax. Application of *DPE* does not equalize the price of educational services. Similarly, the local tax rate is not a measure of effort unless it is assumed that the "sacrifice" per dollar of revenue varies in proportion to the inverse of local wealth, a utilitarian argument with a Bernoullian utility function. It is this confusion about the nature of the price and wealth effects that leads Coons et al. to write that "because [with *DPE*] incentive is stripped of differential wealth obstacles, it is hoped that the distribution of high and low expenditure districts will become random as regards wealth" (p. 203). Only if the price elasticity and the adjusted wealth elasticity are exactly offsetting would *DPE* achieve complete wealth neutrality.[7]

---

[6] Equation (3) is a special case of Henri Theil's result on specification bias in least squares regression. Since the regressions can be calculated using observations on all towns in the state, the coefficients may be regarded as *measures* of the descriptive statistics rather than as *estimates* of unobservable parameters. The choice of interpretation is irrelevant as long as the operational measure of wealth neutrality is the calculated wealth elasticity of equation (1).

The analysis of this section has shown that the relevant aspects of the local demand for education can be summarized by two key parameters: the price elasticity β_p and the adjusted wealth elasticity β_w. A knowledge of these parameters is required to design a system of matching grants that achieves any desired degree of wealth neutrality and, more generally, to assess the impact on wealth neutrality of any system of matching grants. I turn now to the problems of estimating these parameters.

II. Estimating the Effects of Wealth and Intergovernmental Grants

Although there have been many studies of the expenditures of state and local governments, there are no satisfactory estimates of the effects of intergovernmental grants on local government spending. The essential feature of an "open end" matching grant is that it lowers the net price paid by the local government. In contrast, a block grant has no price effect (unless the community would otherwise have spent less than the amount of the grant). The "closed end" matching grant, i.e., a matching grant with a maximum intergovernmental transfer, has aspects of both the open end matching and block grants. More specifically, for a community that does not reach the maximum, the upper limit is irrelevant and the grant is equivalent to an open end matching grant. For a community that exceeds the maximum, the grant has no marginal price effect and acts instead as a block grant.

In the empirical analysis of local government spending it is therefore crucial to distinguish grants that are effectively matching grants from grants that are effectively block grants. Moreover, the matching grant should be described in terms of the price that it implies for each local community. Unfortunately, previous empirical studies of local government spending have generally ignored the distinction between block grants and matching grants. They therefore described all aid by the volume of funds transferred and did not isolate a price effect.[8] The only studies that distinguished matching grants and used the matching rate as a price variable (see Robert Inman (1970, 1971), David Stern) have constrained the specification of the expenditure equation in a way that precludes an independent estimate of the price elasticity.

---

[7] Coons et al. also discuss a more general form of *DPE* plan in which $P_i=f(t)W_i$ where $f(t)$ is any function of the rate of tax t but a function that is independent of W_i. Although the choice of an $f(t)$ function would obviously affect the resulting wealth neutrality, it might not be possible to design an $f(t)$ that achieves complete wealth neutrality. Analysis of the effects of such a plan is more complicated than with the basic percentage equalization form of *DPE* because $P_i=f(t_i)W_i$ implies that the town does not face a fixed price but rather a price that varies as it changes the quantity of education that it wants to purchase, i.e., as it changes t. The important point here is that the proposed *DPE* plans are unlikely to achieve a satisfactory degree of wealth neutrality because they have not been designed with that in mind.

[8] This is true of the studies of educational spending by Edward Renshaw, George Bishop, and Jack Osman as well as more general studies of government spending by Seymour Sacks and Robert Harris, Roy Bahl and Robert Saunders, James Henderson, Edward Gramlich (1968, 1969), and others.

The current study relates educational expenditure per pupil in Massachusetts towns to the price implied by the matching rate, the local property value per pupil, and other potential determinants of local school spending. The data for Massachusetts are particularly suitable for estimating the effect of matching grants. The matching rate varies substantially among the local communities; in the sample of 105 towns used in the current study, the matching rate ranged from zero to 0.38. This implies that the local price per dollar of educational spending varies between $0.62 and $1.00.

It is important to examine the source of this variation in local matching rates. Clearly, if the state sets the matching rate as a function of variables that are themselves determinants of local spending, the expenditure equation may be underidentified. For example, if the local price were exactly proportional to the local wealth variable, it would be impossible to estimate separate coefficients for price and wealth in a linear or log-linear regression. If the price variable were some non-linear function of wealth, separate coefficients for price and wealth could be estimated in a linear equation only because the analysis introduces the implicit a priori information that the expenditure relation is linear. The justification for such an a priori restriction might be very weak. The linear or log-linear specification, which is generally used only as a convenient approximation, would in this situation be the source of the crucial identifying restriction. Stated somewhat differently, if the legislature uses a non-linear matching grant because it perceives a non-linear effect of wealth on local spending, why should the econometric analysis ignore this information and reject the legislature's perception?

Posing the problem in this way suggests an answer. The actual development of formula matching grants reflects history, legislative compromise, and accident rather than empirical analysis and economic logic. If the matching rate varies sufficiently and is not highly correlated with the other explanatory variables, the possibility of underidentification is not likely to be a problem of practical significance. The Massachusetts experience is a good illustration. Although the basic formula makes state matching proportional to local wealth, a variety of limits and special provisions so attenuates this relation that the correlation between price and wealth in 1970 was only 0.38.[9]

In all of the equations presented below, the dependent variable is current educational expenditures per pupil E, including local, state, and federal funds. The wealth variable W is the official "equalized" or "true" property value per public school pupil, and the price variable P is equal to one minus the local marginal matching rate.[10] Current income INC is measured as median family income in the town. The values of state block grants *SBG* and of federal grants *FG* are also included.[11] Since the federal grants are not block grants but are direct funding of special programs in eligible communities, their effect on spending should be more substantial than that of the state block grants.[12]

---

[9] Legislative compromises modified the basic proportionality formula by imposing both upper and lower limits on the matching rate and on the levels of expenditure that would be matched. The 1966 law also provided that towns would not receive less in the future than they had in a previous base year.

[10] For those towns for which the state aid was effectively a block grant, i.e., for which an additional dollar of local spending would induce no additional state aid, the price is one. For all other towns, the state aid is a proportional matching grant and the price is calculated as the ratio of local current "reimbursible expenditures" (as defined by ch. 70 of the Massachusetts laws) to the sum of that expenditure and the state matching aid implied by the legislative formula. This implicitly assumes that the market prices of educational goods and services are the same in all towns within the state. While this is quite reasonable for the manufactured goods used by the schools, the assumption is more doubtful for teachers' salaries and some other locally purchased services. While the salary of teachers varies

If the local voters assume that they bear less than the full cost of taxes raised from nonresidential property, those towns in which the residential property proportion of the local tax base *RES* is relatively high should prefer a lower level of school spending. If local residents assume that they bear none of the local tax on nonresidential property, the price of educational services is effectively lowered by a fraction equal to the nonresidential property proportion of the local tax base. Local residents will however bear the tax on nonresidential property to the extent that it affects local wages and prices and, more importantly, through its long-run effects on the size of the nonresidential property tax base.[13]

Towns in which the use of private schools is more common may also tend to offer a lower level of school spending although this is offset to the extent that parents support high quality public primary education and then send their children to private secondary schools or support high quality public secondary education but use private (including parochial) schools for the lower grades. The number of private school pupils per capita *PRIV* is included to assess the net effect of these forces. A greater number of public school pupils per capita *PUP* will generally result in less taxable property per pupil (a lower value of *W*). It may also reduce spending by lowering family income per pupil or, alternatively, raise spending by increasing the fraction of families with school age children. The final variable included in the equation is a measure of the recent growth in the number of pupils; more specifically, *GROW* is the ratio of the number of pupils to the corresponding number five years earlier. If there is a reluctance to raise tax rates quickly, a rapid growth of pupils will temporarily reduce per pupil spending. To allow for a more general lagged response of educational spending to all of the explanatory variables, a proportional adjustment model is examined by including the lagged value of the dependent variable among the regressors.

III. The Parameter Estimates

The estimated equations are specified as linear in the logarithms of the variables. The data are a sample of 105 Massachusetts towns that contain 72 percent of the state population.[14] When values for more than one year are used in the same equation, all dollar amounts are converted to 1970 dollars.[15]

---

among towns, it is not clear how much of this variation reflects quality differences. In some estimates not reported in the paper, an educational input price index was included and found to be insignificant and sometimes to have the "wrong" sign; this suggests that much of the price variation reflects quality differences and therefore local choice.

[11] For the purpose, state block grants are defined for 1970 as the value of the matching aid for those towns for which the marginal matching rate was zero. Before 1970, *SBG* is block grants provided under the previous "foundation" plan. Although the Massachusetts rules imply that the receipt of a block grant instead of a matching grant now reflects very high or very low spending by a local community, no attempt was made to develop a simultaneous model. The insensitivity of the estimate to 1) the use of the mixed 1965–70 sample, 2) the restriction of the sample to towns with matching grants, and 3) the use of instrumental variable estimation, indicates that this is not likely to be a source of significant bias.

[12] The federal grants variable includes some state grants for special programs.

[13] The data for *RES* are based on an official 1958 survey and may for some towns be inaccurate for 1965 and 1970.

[14] The remaining small towns were omitted because data were not available for all the variables or, for a few towns, because of their relation to a regional school district.

[15] Income and wealth variables are deflated by the Consumer Price Index for Boston with 1970 equal to 1. (over)

TABLE 1—LOCAL DEMAND FOR EDUCATION

Note: The dependent variable in all equations is real educational expenditure per pupil; in equations 1.6 and 1.7, the dependent variable is adjusted for the effect of wealth. All variables are in logarithms. See text for definitions and descriptions of samples and independent variables. Standard errors are shown in parentheses. When a lagged dependent variable is included, the long-run elasticities are shown in square brackets; constant terms are not shown; N.A. = not applicable; see text for explanation

Table 1 presents alternative estimates of the basic expenditure relation, equation (2) of Section I. Despite important differences in the methods of estimation, the estimated price and wealth elasticities of these equations are quite stable. More specifically, the price elasticity estimates are between −0.940 and −1.599 while the wealth elasticity estimates are between 0.202 and 0.361.[16]

Since the estimates are quite stable and most of the parameters are only of incidental interest in the current study, it is useful to examine first the basic estimates in equation 1.1 and then to comment on the different estimating methods used for the other equations in the table. The estimates of equation 1.1 are based on a single cross-section sample of all the towns for 1970. The elasticity with respect to wealth is very low (0.28) but the price elasticity is quite high (−1.00). The income elasticity is also quite low (0.48), casting substantial doubt on the common assertion that "... as a statistical matter, the poorer districts are financially unable to raise their taxes high enough to match the edu-

---

Educational expenditure variables are adjusted by an education price index that combines the wholesale price index and an index of New England urban teachers' salaries with common weights based on the input ratio in Massachusetts.

[16] These estimates all use the price variable implied by the legislative formula. Before 1970, the legislature did not appropriate sufficient funds to provide the matching grants implied by the legislation. If towns assumed that this incomplete funding would continue, they would act as if a different price would prevail. The calculations of this section were repeated with the price (when less than one) defined as the ratio of local reimbursible expenditure to the sum of local reimbursible expenditure plus the *actual* state matching aid. These estimates are quite similar but with slightly higher price elasticities; an appendix reporting these results is available from the author.

cational offerings of the wealthier districts" (*Serrano vs. Priest*, p. 514).[17]

The elasticity with respect to block grants (*SBG*) is very low and less than the coefficient of federal grants *FG*.[18] The negative elasticity with respect to the proportion of the tax base that is residential (*RES*) confirms that voters do regard nonresidential taxes to be less costly than residential taxes. Although measurement error[19] may have biased this coefficient toward zero, it seems safe to infer that the true elasticity is actually less than the price elasticity; this implies that voters assume that a significant part of the nonresidential tax is shifted to residents in the long run. Although a larger number of pupils attending private schools (*PRIV*) appears to depress educational spending, the coefficient is unstable and the sign varies among the equations. An increase in the ratio of pupils to population (*PUP*) appears to increase per pupil spending but the coefficient is small and insignificant. Finally, the rate of growth of the number of pupils (*GROW*) causes a reduction in per pupil spending; the coefficient (−0.34) implies that an increase of 10 percent in the five-year rate of growth would depress expenditure per pupil by less than 4 percent.

The second equation tests for a distributed lag response of local spending by adding the 1965 value of the logarithm of educational expenditures (denoted E_{-5}) to the equation. To avoid a positive bias in the coefficient of this variable,[20] the equation was estimated by an instrumental variable procedure with the lagged dependent variable treated as "endogenous." The estimates show that the lag is very short and insignificant. None of the other coefficients is appreciably different from equation 1.1.

Before the current method of state aid was introduced in 1966, there were no matching grants. In 1965, all towns faced the same price. With a pooled sample of 210 observations for 1965 and 1970, the variation in the price variable reflects the legislative change and the increases in the price of educational services[21] as well as the differences in matching rates among towns in 1970. The parameter estimates presented in equation 1.3 confirm the previous conclusions. The price elasticity is high ($\hat{\beta}_p = -1.25$) and the wealth and income elasticities are relatively low.

The 1966 legislative change provides a further method of testing whether the estimated wealth and price elasticities are biased because of the relation between price and wealth implied by the Massachusetts aid formula. Since all towns faced the same price in 1965, the estimated effect of wealth for that year would not be "contaminated" by a price effect. Equation 1.4

---

[17] Although the quoted assertion obviously refers to California, similar statements have been made about the nation as a whole. In Massachusetts, the sample town with the lowest per pupil wealth in 1970 ($10,848) spent $760 per pupil. The town with the highest per pupil wealth ($85,630) spent $1130. If the low wealth town spent as much per pupil as the high wealth town, the additional $370 per pupil would only have consumed an additional 4.2 percent of family income even if there were no additional state aid. This stands in contrast to the conclusion in the *Serrano vs. Priest* decision: "The poor district cannot freely choose to tax itself into an excellence which its tax roles cannot provide. Far from being necessary to promote local fiscal choice, the present financing system actually deprives the less wealthy districts of that option" (p. 524).

[18] The block grant elasticity actually implies a marginal propensity to consume these funds of approximately 0.6. This high value is misleading because in 1970 most block grants were paid to towns that passed the limit of matching aid; the block grants are endogenous and the coefficient is biased upwards. The estimates in the 1965 equations show that an unbiased estimate is not significantly different from zero and that the endogeneity of this variable does not affect the coefficient of any of the other variables.

[19] See fn. 13.

[20] A positive bias would occur if the disturbance term were correlated with the lagged dependent variable. In the current context, this could reflect a common town-specific component in each year's disturbance. For a full statement of such a model, see Pietro Balestra and Marc Nerlove.

[21] See fn. 11.

presents the estimated coefficients for 1965.[22] The estimated wealth elasticity (0.20) is very similar to the value in 1970.[23] Although the lagged dependent variable ($ln\ E_{1960}$) introduced in equation 1.5 implies a significant lag in the response, the long-run elasticities (shown in square brackets) are very similar to the estimates of equation 1.4. In particular, the long-run wealth elasticity is estimated to be 0.29. These estimated wealth elasticities can be treated as "extraneous" estimators of the 1970 wealth effect and used to derive new estimates of the 1970 elasticities with respect to the price and other variables. Equation 1.6 uses the long-run wealth elasticity of equation 1.5; the dependent variable is $ln\ E_{1970} - 0.288\ ln\ W_{1970}$. Since the extraneous estimator is quite similar to the unconstrained estimate of equation 1.1, this substitution has little effect on the price and other elasticities.

As a final check on the estimated price and wealth elasticities, the equation was reestimated for only those towns which effectively received matching grants in 1970; for all of the observations used to estimate equation 1.7, the price variable was less than one. Since for these towns the price is related by an almost exact formula to local wealth, an extraneous estimator of the wealth elasticity is required; the estimate of 0.202 from equation 1.4 was used. The estimated price elasticity (−1.038) and the other coefficients are quite similar to the values obtained for the full 1970 sample.

In all of these equations, the price, state block grants, and use of private schools were treated as exogenous variables. When these variables are treated as endogenous in equation 1.8, the results are not substantially changed. The price elasticity is increased and the wealth elasticity rises somewhat less. The larger standard errors suggest that these differences are not statistically meaningful.

The price elasticity will be used in the next section to assess the effects of different grants on wealth neutrality. The other coefficients of the demand equation are not relevant as such but only through their contribution to the adjusted wealth elasticity. Recall from Section I that the adjusted wealth elasticity (β_w) is defined as follows: If the basic demand equation is

$$(6) \quad ln\ E_i = \beta_0 + \beta_1\, ln\ W_i + \beta_p\, ln\ P_i + \sum_{j=3}^{k} \beta_j\, ln\ X_{ji} + \epsilon_i$$

the adjusted wealth elasticity is

$$(7) \quad \beta_w = \beta_1 + \sum_{j=3}^{k} \beta_j \gamma_{x_j w}$$

where $\gamma_{x_j w}$ is the elasticity of the variable X_j with respect to W. Although β_w could be constructed by estimating individual $\gamma_{x_j w}$ and combining them with β_j as presented in Table 1, there is a simpler and more direct method that yields exactly the same estimate of β_w. In the ordinary least squares estimate of the equation:

$$(8) \quad ln\ E_i - \beta_p\, ln\ p_i = b_0 + b_1\, ln\ W_i$$

the value of b_1 is an estimate of β_w. It follows from Theil's formula for specification bias that this estimate of β_w is exactly the same as would be obtained by direct substitution in equation (7).

The adjusted wealth elasticity has been calculated in this way for three of the values of $\hat{\beta}_p$ presented in Table 1. The basic estimate of $\hat{\beta}_p = -1.000$ based on the 1970 cross-section (equation 1.1) implies an adjusted wealth elasticity of $\hat{\beta}_w=0.370$. The pooled sample of 1965 and 1970 observations (equation 1.3) implied $\hat{\beta}_p=-1.246$, the corresponding adjusted wealth elasticity is $\hat{\beta}_w=0.414$. Finally, with the value of $\hat{\beta}_p=-1.038$ obtained in equation 1.7, the adjusted wealth elasticity is 0.377.[24] Over the relevant range, therefore, the estimated price elasticity is approximately three to five times as large as the corresponding adjusted wealth elasticity. The implications of these estimates are the subject of the next section.

---

[22] There is no coefficient for the price variable because it was a constant in 1965.

[23] The coefficient of the block grant variable is now insignificant. This reflects a correction of the bias that arose from the endogeneity of the block grant in 1970; see fn. 18. The elasticities with respect to income, federal grants, pupils per capita, and the growth rate of pupils are very similar to the 1970 values. The two remaining variables, the residential portion of the tax base and the relative number of private school pupils, are insignificant.

IV. Analysis of Alternative Matching Grant Plans

This section uses the parameter estimates to assess the effect of alternative matching grants on the degree of wealth neutrality and then discusses the tradeoff between wealth neutrality, efficiency loss, and income redistribution. It is useful to begin by restating that wealth neutrality is measured as the elasticity of expenditure per pupil with respect to wealth (local tax base per pupil). It was shown in equation (4) that the value of wealth neutrality α_1 is related to the price and adjusted wealth elasticities of demand (β_p and β_w) by

$$\alpha_1 = \beta_w + \beta_p \gamma_{pw} \tag{9}$$

where γ_{pw} is the elasticity of price with respect to wealth that is implied by the matching grant plan.

With no wealth neutralizing matching aid (i.e., $\gamma_{pw}=0$), $\alpha_1=\beta_w$: the actual elasticity of educational expenditure with respect to wealth would simply be the adjusted wealth elasticity. The estimates of β_w reported in Section III therefore indicate that in the absence of state policy the wealth neutrality measure would be between $\alpha_1=0.370$ and $\alpha_1=0.414$. The high ratio of the price elasticity to the adjusted wealth elasticity implies that matching grant plans with even relatively low elasticities of price with respect to wealth (γ_{pw}) would substantially increase wealth neutrality (reduce α_1).[25] In 1970, the Massachusetts value of γ_{pw} was only 0.18 but this was sufficient to reduce α_1 to only 0.19.

Equation (9) shows that complete wealth neutrality ($\alpha_1=0$) is achieved when $\gamma_{pw}=-\beta_w/\beta_p$. The estimated elasticities therefore imply that complete wealth neutrality would occur with γ_{pw} somewhere between 0.33 and 0.37. It is clear that if complete wealth neutrality is preferred or is mandated by the court, it could be achieved by a relatively small increase in γ_{pw}.

The estimated elasticities also show that the basic percentage equalization form of district power equalizing would have the peculiar effect of causing educational spending in towns with low wealth to be very much higher than in towns with high wealth. Since the basic district power equalizing formula implies $\gamma_{pw}=1$, the estimates of β_p and β_w imply a value of α_1 between -0.630 and -0.832. Since the average wealth in the ten wealthiest towns is approximately four times the average wealth in the ten poorest towns, these values of α_1 indicate very substantial spending differences. While these implied

---

[24] The R^2 values associated with these equations provides an overestimate of how much of the variation in expenditure per pupil is due to wealth differences net of the effect of matching grants; the R^2 values are between 0.293 and 0.305. The simple r^2 between W and EPP in 1970 was 0.359. It is clear that the evidence does not support the common assertion to the effect that "The level of school expenditure in a district is largely determined by the wealth of the local tax base" (Wise (1968), p. 121). For a detailed analysis of the relation between school spending and individual income, see the author.

[25] This is contrary to the type of conclusion reached in Benson et al., André Daniere, and B. Levin et al. However, these studies did not use estimated demand elasticities and generally relied upon an ad hoc rule of behavior to describe the response of local governments to a change in state aid. Although there is a price effect in Stern's analysis, the effect is essentially imposed by the form of the function and not estimated from the sample.

α_1 values might exaggerate the actual outcome,[26] the evidence clearly implies that power equalizing grants would not neutralize wealth but could create a stronger (but negative) relation between wealth and spending than currently exists.[27]

A. *Incomplete Wealth Neutrality*

If the courts do not require complete wealth neutrality, the state legislatures will have the option of selecting the desired degree of wealth neutrality by balancing this against the other effects of variations in the matching rate. The rest of this section discusses the primary factors that should be considered in this choice of a price formula.

The current analysis has implicitly ignored differences in tastes for education. If wealth and the taste for education are correlated, a more appropriate definition of complete wealth neutrality might be the elimination of wealth effects per se but not the association between wealth and education that is due to correlated taste differences. Since the relation between wealth and the unobservable taste cannot be estimated empirically, the adjustment for correlated taste differences could not be made precise. A positive correlation between wealth and the taste for education would however imply that complete wealth neutrality was achieved with $\alpha_1 > 0$; for a negative correlation, $\alpha_1 < 0$. Whether the definition of complete wealth neutrality should be modified in this way is clearly a matter of ethical preference and legal judgment.

Of greater importance is the effect of intergovernmental grants on allocative efficiency. Since matching grants distort the price of education faced by local towns, they result in an excess burden. The magnitude of the efficiency loss due to any particular price distortion depends on the parameters of the ***individual*** demand curves,[28] the method of local budget determination, and the opportunities for residential relocation.[29] In addition, the usual aggregate of individual consumer surplus losses would require modification if households undervalue (or overvalue)[30] education or if there are significant externalities. Despite these complexities, it seems clear that the excess burden would generally increase as wealth neutrality is increased, i.e., as γ_{pw} rises and enlarges the average price distortion.[31]

---

[26] The value of β_p might not remain constant over a much wider range of prices than was observed in the sample. Moreover, the short-run response of price *increases* might be less than the long-run response even if price decreases have the same short-run and long-run responses. The outcome would therefore depend also on the average rate of matching, i.e., on the parameter k of equation (5). Moreover, if the price were very high for wealthy towns, a substantial switch to private schools might occur.

[27] These estimated effects of *DPE* would of course be different if, instead of the basic percentage equalization form of *DPE*, the price formula were $p_i = f(t_i) \cdot W_i$; see fn. 7. The current analysis has shown that if $f(t)$ is a constant, i.e., $f'(t_i) = 0$, educational spending will decline with wealth. This implies that t_i will vary inversely with W_i. If the $f(t_i)$ is designed to "reward effort", i.e., if $f'(t_i) < 0$, the inverse relation between E_i and W_i would be made even stronger.

[28] Note that the ***individuals'*** price elasticities can be very much less than the estimated town elasticity because individuals can take the level of school spending into account in selecting their residential location.

[29] The method of budget determination by voting will generally not yield a Pareto optimal level of spending for the community in the absence of a distortionary matching grant. This point is developed by Robin Barlow and extended in comments by Yoram Barzel, Theodore Bergstrom, and Noel Edelson. It is surprising that neither Barlow nor any of the discussants of his paper consider the issue of residential location. The effect of individual choice of community is to reduce the welfare loss associated with uniform expenditure for each town. If individuals with different wealth levels choose to reside in the same town, differences in taste for education must partly offset the effect of wealth differences. Because differences among communities in their tax bases and tax rates are capitalized and reflected in the prices of residential housing, the process of "shopping for public services" by residential location is not sufficient to yield a Pareto optimal level of local spending.

[30] Although it has long been argued that parents may, out of ignorance or selfishness, spend too little on their children's education, recent research strongly suggests that within the observed range of per pupil expenditure there is no relation between school spending and educational gain (see J. S. Coleman et al., Frederick Mosteller and Daniel Moynihan). Ignorance and good intentions may cause overspending rather than underspending.

Although wealth neutralizing matching grants generally redistribute funds toward low wealth towns,[32] a careful analysis of the final incidence of the grants may show that the effect on the real distribution of income is both unintended and undesirable. The net funds received by a town will be reflected in the value of local property.[33] The primary gains would therefore accrue to landlords and homeowners in low income communities.

The issue of "horizontal equity" (i.e., the principle that individuals who are alike should be treated in the same way) has received prominent attention in discussions of educational finance. It is commonly suggested that the current system is unfair because two families with the same wealth will pay different tax rates and therefore different total tax dollars for the same education if they live in towns with different wealth per pupil. This argument is essentially illusory since differences in the tax cost of a given level of education will be largely offset by differences in housing prices between the communities. If one town offers the opportunity to obtain education at a lower cost, its houses will sell at higher prices.

Finally, the choice among matching grant plans will imply different total costs to the state government. Since these educational deficits will affect state taxes and other expenditure programs, the size of the deficit will have additional distributional and allocative effects. The size of the deficit can be controlled by changing the average price without affecting the wealth neutrality, i.e., by altering k without changing γ_{pw}. It is clear, however, that with only two "instruments" (k and γ_{pw}) it is not possible to achieve any desired combination of wealth neutrality, average expenditure, and budget deficit. More generally, if complete wealth neutrality is not judicially imposed, the state legislatures must balance wealth neutrality, allocative efficiency, and distributional impact in designing a system of educational finance.

V. Conclusion

Notions of categorical equity have become increasingly common in public discussion and judicial opinion. To incorporate such preferences in public expenditure analysis requires operational measures of categorical equity and explicit attention to balancing categorical equity, allocative efficiency, and distributional impact.

The current paper has analyzed an important example of categorical equity: wealth neutrality in local public education. For this purpose, wealth neutrality was measured by the elasticity of local school spending with respect to local per pupil wealth. The analysis showed that a state can achieve any desired degree of wealth neutrality by using matching grants that cause the net price of educational services to vary with wealth in the appropriate way.

---

[31] The excess burden would therefore also depend on the value of k in the price formula. If k were chosen to make the *maximum* price be 1, the excess burden with any $\gamma_{pw}>0$ would be greater than if k were chosen to make the *average* price be 1. By centering the prices around 1, the average absolute price distortion is less for any γ_{pw}; as a rough approximation, the excess burden is proportional to the square of the absolute price distortion. For some estimates of the welfare loss of distortionary finance, see Eric Toder.

[32] This is obviously so if the grant is completely wealth neutralizing. With partial wealth neutrality, the distribution depends on balancing the effects of higher spending by wealthy towns and higher matching rates for less wealthy towns. It is easily shown that the elasticity of state matching payments with respect to local wealth (η_{sw}) is given by $\eta_{sw}=\alpha_1[E(1-P)/S]+\gamma_{pw}[EP/S]$ where E is the expenditure per pupil and S is state aid per pupil. For sufficiently low γ_{pw}, η_{sw} may be positive. Obviously the net redistribution depends on how any state deficits are financed.

[33] Any reduction in local taxes that results from the matching aid would be fully capitalized. Each additional dollar of educational spending will be worth less than a dollar to the local residents. This value would also be reflected in the price of individual homes or, through its effect on the rents that people would pay, on the value of rental property.

The specific parameter estimates of the educational demand function imply that even complete wealth neutrality can be achieved in Massachusetts with matching grants that involve a relatively low elasticity of price with respect to wealth (between 0.33 and 0.37). The estimated elasticities therefore indicate that the widely advocated district power equalizing form of percentage equalization grant, which has a price-wealth elasticity of 1, would not be wealth neutralizing but is more likely to result instead in an *inverse* relation between local wealth and local educational spending.

There is much that can be done to verify and extend this analysis. The current calculations should be applied to other states to see whether achieving different degrees of wealth neutrality would require more substantial price distortion than in Massachusetts. The empirical analysis should also be extended by using a more complete model in which the price and quality of educational services and the value of local property are treated as endogenous. A better theoretical understanding of the process of residential location, budget determination and property valuation is required as a basis for assessing the allocative efficiency and distributional impact of alternative systems of educational finance.

Finally, the methods discussed in this paper are obviously applicable to any public service in which intergovernmental aid is intended to have a wealth neutralizing effect. The same approach can also be used in the design of matching grants to individuals. Thus, the basis of educational wealth neutrality could be shifted from the school district to the individual.[34] More generally, national health insurance, rent subsidies, and public scholarships for higher education all involve subsidies that intentionally distort the prices that individuals pay in order to achieve greater wealth neutrality. Such programs would benefit from explicit analysis of the way that alternative price systems would affect wealth neutrality as well as allocative efficiency and income distribution.

[34] In contrast to Milton Friedman's original proposal for educational vouchers of fixed value, the state could provide each household with a voucher that specifies a price at which the household could purchase educational services. With appropriate estimates of the individual wealth and price elasticities, the pricing system could be designed to achieve any desired degree of wealth neutrality. Coons et al.'s suggestion of "individual power equalization" raises the same problem as district power equalization; unless the individuals' price and adjusted wealth elasticities are equal, individual power equalizing grants will not be wealth neutralizing.

Household Utility Maximization and the Working Wife

By WENDY LEE GRAMM*

There have been many studies on the labor supply of married women.[1] Typically, they find that the presence of young children in the household is an important factor affecting women's labor force behavior. Yet in many of these studies, the presence of children is not explicitly incorporated into the underlying theoretical framework. In this paper, I develop a model which incorporates children into the decision-making process. It is assumed that the household derives utility from commodities which are produced using time and market inputs.[2] In this model, the presence of a child affects production, and this influence varies with its age. Disaggregated data on over 400 households are used to test hypotheses about the influence of children on the woman's labor force behavior. The data, collected in a survey of married women teachers, are uniquely suited for this study—partly because there is much information not readily available in other bodies of household data, and partly because the sample itself has many desirable characteristics (for the purposes of testing the hypotheses implied by this model).

I. A Utility-Maximizing Model of the Household

In this model, the household maximizes its utility which depends on the amount of home-produced goods H consumed. Home goods are produced using inputs of time of the husband T_1, time of the wife T_2 and/or market inputs X. The household faces a budget constraint which states that expenditures on market goods cannot exceed income (which equals property income rA and the labor incomes of the husband and wife). The household also faces a time constraint which states that the time spent per period at market work plus the time spent per period producing home goods must exhaust the length of the period (which is arbitrarily set at one). The problem can be stated as follows:

$$(1) \qquad \text{Maximize } U(H)$$

subject to:

$$H = g(X, T_1, T_2, a_K, \tau) \quad K = 0, \ldots, L$$

$$rA + w_1(1 - T_1) + w_2(1 - T_2) - p_X X = 0$$

$$(1 - T_2) \geq 0$$

where a_K is the number of children between the ages K and $K+1$, L is the age of the child when it leaves the household, τ is the age of the household (the number of years since marriage), r is the interest rate, A is household assets, w_1 and w_2 are wages of the husband and wife, respectively, and p_X is the price of market inputs. The first relationship is the production function for home goods, the second summarizes the budget and time constraints, and the third states that the wife may choose to spend all her time at home.[3]

---

* Assistant professor of economics, Texas A&M University. I would like to thank Thomas Saving, George Borts, and Arleen Leibowitz for helpful comments, especially on the theoretical section of this paper. The empirical sections are drawn from my dissertation. I am grateful for the assistance I received in this from Frank Brechling, George Delehanty, Clyde Porterfield, Arthur Treadway, and Richard Westin. The research was supported by grants from the Manpower Administration of the U.S. Department of Labor under the Manpower Development and Training Act of 1962, as amended, and from the Texas Research Council.

[1] See, for example, Nedra Belloc, William Bowen and T. Aldrich Finegan, Glen Cain, Malcolm Cohen et al., Thomas Mahoney, Lucy Mallan, Jacob Mincer (1962a), and Richard Rosett.

[2] See Gary Becker and Reuben Gronau for a development of this model.

In this model, the presence of children affects the household decision-making process by affecting the productivity of market inputs and nonmarket time in the production of home goods. Accordingly, the marginal products of inputs may differ for households with different numbers and age distributions of children. For example, compare two households identical in all respects except that one has no children and one has a single child age one year. The difference between the two households' marginal products of inputs in the production of home goods represents the effect that a one-year old child has on the household (relative to a household with no children). The effect of the aging of a child can then be represented by comparing the marginal products for a family with one child age two years with that same family with one child age one year. No specific assumptions are made here about the relative sizes of the marginal products of inputs for utility maximizing households with children of different ages. However, one would expect the marginal products of time and certain market inputs to be greater for households with children vis-à-vis childless households. One might also expect that for households alike in all respects other than the ages of the children, the marginal products of the husband's and wife's times are largest for households with very young children while the marginal product of market inputs is largest for households with older children.[4]

The age of the household, defined as the number of years since marriage, affects the productivity of the husband and wife in producing home goods. Economists often assume that specific on-the-job training raises the marginal product of labor in that job. Also, education makes the individual a more efficient producer and consumer. For similar reasons it is assumed here that with age the husband and wife acquire skills and experience which causes the marginal products of their time in the production of home goods to increase.[5]

The following are the necessary conditions for the maximization of utility.[6]

$$(2) \quad U_H g_X - \lambda p_X = 0$$

$$(3) \quad U_H g_{T_1} - \lambda w_1 = 0$$

$$(4) \quad U_H g_{T_2} - \lambda w_2 - \theta = 0$$

$$(5) \quad rA + w_1(1-T_1) + w_2(1-T_2) - p_X X = 0$$

$$(6) \quad \theta \geq 0; \qquad = 0 \quad \text{when} \quad (1-T_2) > 0$$

where U_H is the marginal utility of H and where g_X, g_{T_1}, and g_{T_2} are the marginal products of X, T_1, and T_2, respectively. The interpretation of the necessary conditions is straightforward. Conditions (2)–(4) state that in the interior (when $\theta=0$ and $1-T_2>0$) the ratio of marginal utilities of T_1, T_2, and X must equal the ratio of prices. Conditions (2)–(4) also reduce to the condition that the marginal products in producing home goods must equal the ratio of prices. Since the multiplier λ is the marginal utility of income, these conditions imply that for an interior solution the marginal utility produced by an hour of market work must equal the marginal utility produced with an hour of home time. Equation (5) restates the budget constraint, while (6) is the boundary condition which states that when the wife does not work in the market, the multiplier θ is greater than zero. When this is so, (4) states that

---

[3] Since the purpose of this paper is to derive the wife's labor supply behavior and not the husband's labor supply, it is assumed that the husband always spends some time at market labor.

[4] One might expect this to be so because time is essential to the attainment of utility from some commodities (like "childness" or "TV watching"). So the husband's and wife's times are less substitutable for market purchased time and goods and have higher marginal products. As the children age and are more able to care for themselves (really as the children's ability to produce childness for the household increases) the marginal products of the adults' time in producing and consuming this commodity decline. See Arleen Leibowitz (1972) and the author (1974) for other discussions of this issue.

[5] See Leibowitz (1974) and Robert Michael for the effect of formal education on household decisions. Formal education tends to increase the quantity of labor supplied because it is market oriented. In other words, formal education tends to raise the productivity of labor in the market more than the productivity at home. The kind of education obtained with age is like job-specific training and increases efficiency in the production of nonmarket commodities. For example, homeowners may become expert handymen as they get older. See Mincer (1962b) for a discussion of job-specific training.

[6] The necessary conditions for the problem as it is set up in equation (1) contains another multiplier λ_2 associated with the first constraint, the production function. This multiplier has already been solved out of the system of necessary conditions given here (the multiplier λ_2 is equal to the marginal utility of home goods).

$$U_H g_{T_2} > \lambda w_2 \tag{7}$$

or when the marginal utility of an extra hour of home time exceeds the marginal utility of an extra hour of market work, the wife will not work in the market. When the wife is spending some time at market labor, then $\theta=0$, and these conditions say that the marginal utility of an extra hour of home work time just equals the marginal utility of an extra hour's pay.

The demand for the wife's home time can be derived from the necessary conditions (2)–(6) and is a function of wages, price, interest rate, household assets, household age, number of children of different ages, and parameters of the utility and production functions. The comparative statics for the interior solution are also derived by totally differentiating the necessary conditions and using Cramer's Rule. Some of the more important relations are discussed below:

(a) The sign of the income effect $(\partial T_2/\partial A)$ may be positive or negative, depending on the signs and relative sizes of the second partials of the utility and production functions. The degree to which market inputs are substitutes for time in the production of commodities is important in determining whether or not the wife desires more home time when assets increase.

(b) The effect of an increase in w_1 or w_2 on T_2 depends on the sign and relative sizes of substitution and income effects. When the husband's wage increases, it causes his nonmarket time to be more expensive. In producing home commodities, the time of the wife or market inputs may be used in place of the husband's time. If time of the wife is substitutable for husband's time and if market goods are not good substitutes for time, then the substitution effect (of an increase in the husband's wage on the wife's nonmarket time) will be positive. If the income effect is positive or smaller than the substitution effect $\partial T_2/\partial w_1$ will be positive.[7] The effect of an increase in the wife's own wage on her nonmarket time depends on relative sizes and signs of the income and substitution effects (but the own substitution effect is negative due to second-order necessary conditions).

(c) The effect of children on the nonmarket time of the wife is the primary concern of this paper. Of particular interest is the effect of a change in the number of children age K in the household given by equation (8) where U_H is the marginal

$$\frac{\partial T_2}{\partial a_K} = [-U_H g_{Xa_K} D_{XT_2} - U_H g_{T_1a_K} D_{T_1T_2} - U_H g_{T_2a_K} D_{T_2T_2}] \div D \tag{8}$$

utility of home goods; g_{Xa_K} is the change in the marginal product of input X due to a change in a_K; and D_{XT_2}/D is a substitution effect between the wife's time and market inputs in the production of home goods.[8] The coefficients $g_{T_1a_K}$, $g_{T_2a_K}$, $D_{T_1T_2}$, and $D_{T_2T_2}$ are similarly defined. It is expected that a household with a child age K will have larger marginal products of all inputs than households with no children (so $g_{T_1a_K}$, $g_{T_2a_K}$, and g_{Xa_K} are greater than zero). If the weighted own substitution effect $(-U_H g_{T_2a_K} D_{T_2T_2}/D)$ dominates (this may be due to a large value for $g_{T_2a_K}$) or if the wife's time is substitutable for other inputs, then $\partial T_2/\partial a_K$ will be positive and the wife will spend more time at home.

---

[7] The income effect of an increase in wage on the nonmarket time of the wife may be positive when there are young children in the home, especially if one of the home-produced commodities is childness, a utility-providing output which takes inputs of time and children to produce. If households don't like children, the income effect may be negative since then the wife may go to work and hire a babysitter.

The effect of the aging of a child can be derived from equation (8). If a child ages one year, then the effect on the nonmarket time of the wife would be equal to the effect of a one unit increase in a_K plus the effect of a one unit decrease in a_{K-1} or $(\partial T_2/\partial a_K - \partial T_2/\partial a_{K-1})$. We can thus derive how the labor supply behavior of the wife changes as the child ages.

(d) The effect of the age of the household on the nonmarket time of the wife is similar to the effect of children as described above. It is made up of two weighted substitution effects.

$$(9)\quad \frac{\partial T_2}{\partial \tau} = \frac{-U_H g_{T_1\tau} D_{T_1T_2} - U_H g_{T_2\tau} D_{T_2T_2}}{D}$$

I am assuming that $g_{X\tau}=0$. The substitution effects are weighted by the change in the marginal products of time due to age (times the marginal utility of home goods). One would expect $\partial T_2/\partial \tau$ to be positive implying that women of older families would tend to spend less time at market labor, *ceteris paribus*.

Elasticities of demand can be derived from the necessary conditions. Of particular interest is the wife's labor supply elasticity $\epsilon_{h_2w_2}$ which is derived from the elasticity of demand for her nonmarket time with respect to her wage $\epsilon_{T_2w_2}$. The supply elasticity is:

$$(10)\quad \epsilon_{h_2w_2} = -\frac{T_2}{1-T_2}\left[\frac{w_2(1-T_2)}{Y}\epsilon_{T_2Y} + \frac{w_2T_2}{Y}\sigma_{T_2T_2}\right]$$

where Y is full income, ϵ_{T_2Y} is the income elasticity of demand for T_2, and $\sigma_{T_2T_2}$ is the Allen partial elasticity of substitution. Equation (10) implies that the sign of the wife's labor supply elasticity depends on the relative sizes of the income and substitution effects. The size of the coefficient of elasticity depends on the amount of time the wife spends at market labor $(1-T_2)$, the size of the income elasticity of the wife's nonmarket time ϵ_{T_2Y} and the size of the elasticity of substitution in production $\sigma_{T_2T_2}$. Furthermore, if the demand for the nonmarket time of the wife (T_2) is larger for families with children, then the labor supply elasticity will be larger for families with children than for families without children, *ceteris paribus*.

In summary, the wife's labor supply decision (one minus the nonmarket time of the wife) is a function of the husband's and wife's wages, the ages of the children, household age, household assets, prices and the interest rate, and the parameters of the utility and production functions as given below:

$$(11)\quad h_2 = 1 - T_2 = h_2(w_1, w_2, A, a_K, \tau, p_X, r, \text{parameters of the utility and production functions})$$

Some of the expected signs of the partial derivatives of the labor supply equations are[9]

---

[8] D is the determinant of the matrix of coefficients of the totally differentiated system of necessary conditions and D_{ij} represents the cofactor of the ith row and jth column of this matrix where rows and columns are indexed X, T_1, T_2, λ.

[9] Relations such as $\partial h_2/\partial p_x$ are not discussed here since the labor supply equation was estimated using cross-section data and variables like prices are assumed to be the same for everyone in the sample.

$$\frac{\partial h_2}{\partial w_1} < 0 \tag{12}$$

(if the substitution and income effects of w_1 on h_2 are negative or if a positive income effect is smaller than a negative substitution effect)

$$\frac{\partial h_2}{\partial w_2} ?$$

(also depends on the size of the positive own substitution effect of an increase in w_2 on h_2 relative to the income effect which may be positive or negative)

$$\frac{\partial h_2}{\partial A} ?$$

$$\frac{\partial h_2}{\partial r} < 0$$

$$\frac{\partial h_2}{\partial a_K} < 0$$

(for households with young children relative to households with no children).

In the following section, a linear version of the labor supply equation is estimated using data particularly suited for this analysis.

II. Data and Estimation Procedure

The labor supply equation (11) was estimated using disaggregated cross-section data. The sample we used for this study is composed of 414 female teachers, substitute teachers, and women qualified to teach but not presently working. The information was collected in a survey conducted in 1970.[10] The women are married, living with their husbands, and most reside and teach in public primary schools in the northern suburbs of Chicago.[11] Our sample includes women of varying ages, with and without children, and with varying work loads. In this sample there are 249 women who worked full-time during the survey year, 115 worked part-time (substitute teaching), and 50 chose not to work at all during the year.

To estimate the labor supply of the wife, financial, demographic, and labor supply information was collected for each family. Since the sample is from a relatively homogeneous population in a small geographic area, it was assumed that all individuals face the same interest rate and prices. Because information on parameters of the utility and production functions were not available, these variables were omitted from our estimation.[12] Thus the only explanatory variables are the wage of the husband, the wage of the wife, ages of the children, household assets, and age of the household.

The measure of the amount of market work supplied by the wife (h_2) that is used in the estimation is the proportion of the full-time load that she worked in 1969. The variable h_2 is thus continuous and can assume any value from zero to one. There are observations where h_2 lies between zero and one since substitute and former teachers were also surveyed. Information was obtained about the number of days per week that a substitute taught on the average in 1969 and this was compared with the amount a regular teacher worked to obtain the proper measure of h_2 for a substitute teacher. The measure used for the wife's and husband's wages is the amount they could earn (in thousands of dollars per year) if they worked a full load every day. For substitutes this is the amount she could earn if she substituted all day every day.[13] Information on the value of present assets and the age of the household was given in the questionnaire. Understandably, many women found it difficult to estimate the value of household assets so we expect that these figures are somewhat inaccurate.

---

[10] The survey of working women was conducted by going to the schools and hiring a teacher to help distribute the questionnaires, explain the purpose of the project, and collect completed questionnaires (anonymous and returned to us in sealed envelopes). Substitute and nonworking teachers were reached via mail survey (names were obtained from the schools' administrations). See the author (1971) for a more detailed discussion of the survey.

[11] This sample has several desirable qualities. First of all, it is relatively homogeneous with respect to such variables as job conditions, taste for market work, and educational requirements for the job. Also, the labor supply decision (the desired variable) of married women teachers was then probably much closer to actual employment (the observed variable) than for married women in other occupations. The woman in this sample is much like the woman of our theoretical model: she knows the wage she can earn by working (detailed salary schedules are readily available and actual salaries of the teachers are published in local newspapers); she can get a job if she decides she wants to work; the cost of job search is negligible; she knows the conditions under which she will be working; and she has more freedom to choose the number of hours she works because she can become a substitute teacher. A teacher in this area can register to substitute in several school districts if she wishes and is not penalized for not working every time she is called.

[12] As long as the omitted variables are not systematically related to the included variables then the least squares estimates of the coefficients will be unbiased.

In order to separate out the effect of each child on the labor supply behavior of the wife, we allow a_K to be equal to zero or one only. For families with more than one child, there will be more sets of age variables, one for each child. These are really dummy variables, defined as follows:[14]

$$a_K^i = \begin{cases} 1 & \text{if the } i\text{th child is } K \text{ years old} \\ 0 & \text{otherwise} \end{cases}$$

A child is K years old if it falls into a three-year age bracket. For example, a_{11}^1 denotes the first child who is 10, 11, or 12 years old, a_5^2 denotes the second child who is 4, 5, or 6 years old. There are seven age dummies to represent the ages of the first and second child (1–3 years, 4−6 years, 7−9 years, 10−12 years, 13–15 years, 16–18 years, and greater than 18 years old). Since no family in our sample had a third child older than 18 years old, there are only six age dummies for the third child. We have five dummies to represent the age of the fourth child and four for the fifth child.

Using ordinary least squares, the work of the wife (the proportion of the full-time load she worked) is regressed on her wage, her husband's wage, household assets, age of the household, and the children's age dummies. The general form of the equation estimated is:

$$\text{(13)} \quad h = c_0 + c_1 w_1 + c_2 w_2 + c_3 A + c_4 \tau + b_2^1 a_2^1 + b_5^1 a_5^1 \ldots + b_2^2 a_2^2 + b_5^2 a_5^2 + \ldots + u$$

The regression coefficient of the age dummy b_K^i measures the effect that the ith child (age K) has on the wife's supply of labor relative to the omitted group, *ceteris paribus*. When the whole sample is used in the estimation, the omitted group is the group of families with no children. For example, b_2^1 is a measure of the difference between the work loads of a woman with one child age 2 years and a woman with no children, holding all else constant. The estimates of b_K^1 can be plotted against K to see the effect of the aging of a child on the labor supply of the wife.

III. Work Patterns of Married Women Teachers

The estimation was carried out two ways. First the labor supply equation (13) was estimated using the whole sample. The variable h_2 was then estimated three more times using subsamples of one-child, two-child and three-child families.[15] Subsamples were used to see how labor supply profiles were changed by the presence of other children in the family. Finally, additional equations were estimated to obtain more information on the effects of children on h_2 as compared to the effects of the aging of the household (or the wife).[16]

---

[13] For substitutes, this figure is usually much lower than the wage she could earn as a full-time teacher. This can be expected to influence our results in the following manner: If a sample contains both full-time and part-time teachers, the coefficient of w_2 would be overstated. Likewise, the measured own-wage supply elasticity would overstate the true elasticity. This problem as well as an attempt to measure the extent of this bias is discussed more fully in Section III.

[14] See Arthur Goldberger, pp. 218–27, for a discussion of the use of dummy variables in regressions.

Table 1 lists the regression results for the four samples. In Figure 1 the estimated age dummy coefficients are plotted for the first child only.

Overall, the variables used are quite successful in explaining the variation in the work loads of the teachers. The coefficient for the wage of the husband has the predicted sign and is statistically significant. The coefficient for the age of the household is negative and statistically significant. The estimated coefficient for the household's present assets is negative but is not statistically significant. Since it was difficult for many women to estimate the value of the household's assets and since value of household assets can be expected to be correlated with wages and the household's age, we do not reject the hypothesis that assets affect the labor supply decision of the wife on the basis of these results. More accurate estimates of household assets than we have here are necessary. Our theory did not give us any predictions about the sign of the wife's own wage coefficient. However the estimated coefficient is positive and significant. This result may reflect the choice set that a woman in this sample faces rather than the response to the change in w_2. A woman in this sample can choose to work full-time, part-time, or not at all. If her choice is not to work or to work a full-time load, her hours are determined. If she chooses to be a substitute teacher, however, she is able to vary her work load as she wishes. The wage she earns as a substitute even if she works every day is considerably lower than the wage she could earn as a full-time teacher (even as a full-time teacher at beginning wages, see fn. 13). Substitute teachers may thus be paying a premium for the privilege of working less than the full-time schedule. So the direction of causality may not be that substitutes work fewer hours because the wage is low. Rather the wage is low because they chose to substitute. In order to test this hypothesis, the regression was run using the subsample of substitute teachers. The estimated coefficient of the wife's wage was small and not statistically significant.[17]

One of the more significant results is that the estimated coefficients of the age dummies for each child in most cases increases as the age of the child increases. This implies that for this group of women, the marginal product of women's time in producing home goods is largest for households with young children.

Other results are summarized as follows. The whole-sample results indicate that the presence of the first child seems to be very important in explaining the labor supply

---

[15] The omitted variable for one-child families is a_2^1; and a_2^1 and a_2^2 are omitted for two-child families. The omitted class for three-child families is made up of families whose first two children are in the 5-year old age bracket and whose third child is in the 2-year old age bracket. This means that the coefficients for the whole-sample age dummies are not directly comparable with the coefficients of the subsample age dummies. For example, in the whole-sample regression, the effect of having a 5-year old child instead of no children is $-.398$. The effect of having a 5-year old child instead of a 2-year old first child is equal to the difference in the coefficients $[-.398-(-.525)]=+.127$. This figure can be compared to the results of the regression using the subsample of one-child families where the effect of having a 5-year old child instead of a 2-year old child (the omitted class) is 0.87.

[16] In this sample, the simple correlation coefficient between the age of the household and the age of the wife is .930 and substituting the age of the wife for the age of the household in our equations did not materially affect our results.

[17] There is an additional problem in interpreting this coefficient because the variation in wages for substitute and nonworking teachers is small for this sample. All substitute teachers in a school district make the same wage.

TABLE 1—ESTIMATED REGRESSION COEFFICIENTS: WHOLE SAMPLE, ONE-CHILD FAMILY, TWO-CHILD FAMILY, AND THREE-CHILD FAMILY RESULTS

Variables	All Families	One-Child Families	Two-Child Families	Three-Child Families
Wage of Husband	−.011[c]	−.005	−.013[c]	−.008
Wage of Wife	.079[c]	.097[c]	.080[c]	.059[b]
Household Assets	−.0003	−.001	.000003	−.0001

WHOLE SAMPLE ESTIMATES

ONE-CHILD FAMILY ESTIMATES

TWO-CHILD FAMILY ESTIMATES

THREE-CHILD FAMILY ESTIMATES

FIGURE 1. PLOTS OF ESTIMATED COEFFICIENTS OF AGE DUMMIES FOR FIRST CHILD

decision of the wife. All coefficients except b^1_{17} and b^1_{GT18} are significantly different from the omitted class at at least the .95 level of confidence. The effect of the aging of this child is also marked.[18] The second child does not seem to have a large effect on the wife's labor supply decision. The coefficients of the age dummies for the second child are all close to zero and the T-values are all small. This may be due to the fact that the first child has picked up some of the effect of the second child. Or it may be due to economies of scale to housework or a learning-by-doing effect with respect to child care.

Another interesting result is found by comparing the estimated coefficients of the different subsamples. The mother of two or three children returns to work more quickly than a mother of one child. This is not surprising since mothers of large families may respond to the increased need for income by returning to work while her children are still young. This rapid increase slows down (there is a "flattening out") when the first child is older perhaps because of the presence of the younger children.

Elasticities of supply were evaluated at the mean for the subsamples. As predicted by the theory, the own-wage elasticity of supply is smallest for the subsample of families with no children. (The elasticities were .610 for families with no children, 1.473 for one-child families, 1.025 for two-child families and .728 for three-child families.)[19] Our theory does not provide an explanation for the negative relationship between the number of children in the household and the size of the coefficient of elasticity.

In order to explore the relationship between the ages of the children and the age of the household, several more equations were estimated using the whole sample. First, the age of the household was expressed as dummies, similar to the dummies representing the children's ages. As a first step, the explanatory powers of different groups of variables were compared, with the following results. When the equation contained only wages and assets as independent variables, R^2 was .520. When household-age dummies were added to the equation, R^2 was .550. However, when children-age dummies were added to the equation in place of the household-age dummies, R^2 was .700. Thus the coefficient of partial determination (partial R^2) or relative net contribution of the household-age dummies was .062 with an F-ratio of 2.600.[20] This is to be compared with the partial R^2 for the children-age dummies of .375 with an F-ratio of 7.655. This implies that the addition of children-age dummies added much more towards explaining the variation in h_t than the addition of household-age dummies.

Furthermore, inspection of the results of the original full sample estimates reported in Table 1 reveals that the estimated coefficient of the household's age (τ, not dummies) though small in magnitude is nonetheless significantly different from zero at the .99 level of confidence. This indicates that the age of the household is a factor affecting the labor supply decision of the married female in this sample and this factor is indeed distinct from the effect of the various ages of her children.

---

[18] T-tests were performed on the estimated coefficients of the age dummies to see whether or not coefficients representing the ith child are significantly different from each other. For the first child, the coefficients of dummies representing adjacent ages are usually not significantly different from each other. For example, the effect of the two-year old first child is not significantly different from that of the five-year old child. Dummies for nonadjacent ages, however, are generally significantly different from each other at the .95 level. This lends further support to the view that the effect of a child on the wife's supply of labor does indeed depend on his age. The age effect is not as strong for the other children.

[19] Since all subsamples included both substitute and full-time teachers, these elasticities may be overestimated.

A Dynamic Analysis of Taxation

By OSVALDO H. SCHENONE*

In a paper published in this *Review*, Jacob Stockfisch uses a two-sector model of a competitive economy which devotes a constant fraction of income to capital accumulation to show, *inter alia*, that "A general tax on consumer items makes it possible for a given level of money investment to buy more real physical assets. Economic growth will be encouraged and the economy will have a larger physical stock of capital with the passage of time" (p. 298).

One of the purposes of this paper is to present an alternative model which gives the result that a general tax on consumption is dynamically neutral, leaving the path of capital accumulation unaffected.

Stockfisch's result hinges on the peculiar savings behavior he assumed. It can be shown that models of capital accumulation in which savings is assumed to be equal to a certain fraction of income (such a fraction may be either constant or a function of the interest rate and/or the distribution of income) give the result that consumption tax favors capital accumulation and growth.[1] This result, however, does not hold in the intertemporal optimizing model employed in this paper.

Nonetheless, a consumption tax is sometimes proposed to foster capital accumulation and growth along the lines suggested by Stockfisch. As stated by R. J. Chelliah, "When we look upon commodity taxation as a weapon for promoting economic growth, its justification lies in the fact that it has a tendency to restrain consumption" (p. 86). Or in the words of John Due, "The tax structure must reduce private consumption. . . . Thus, the tax structure must be designed to strike the portion of income spent on consumption" (p. 33).

On the other hand, arguments have been produced showing that a consumption tax would not have any effect on the path of capital accumulation. This is essentially Nicholas Kaldor's contention about the neutrality of the expenditure tax. Accordingly, the replacement of an income tax by an expenditure tax will increase savings. Richard Goode writes, "It is usually taken for granted that this policy will promote savings, but the basis of the belief is not obvious and is worthy of attention" (p. 232).

The preceding exposition points out the necessity of a systematic analysis of the effects of taxation in the long run, which is precisely the topic of this paper. In the context of an intertemporal optimizing model, I analyze the welfare implications of tax-induced changes in the path of capital accumulation and show the dynamic neutrality of a consumption tax. The model is also used to compare the welfare costs of income taxation and investment taxation.

The results show that the welfare cost per dollar of tax revenue of income taxation is smaller than the welfare cost per dollar of tax revenue of investment taxation. It is also shown that an investment tax at a constant-over-time rate is equiva-

* Visiting professor of economics at the Universidad Católica de Chile. This paper is based on part of my Ph.D. dissertation. I wish to acknowledge my gratitude to the members of my thesis committee, Stanley Fischer, William Brock, and Stephen Magee for guiding me throughout this study. I would also like to thank Arnold Harberger and George Borts for their comments and suggestions. A referee's comments were also very helpful.

[1] This has been shown in the first chapter of my dissertation.

lent to a consumption subsidy at a decreasing-over-time rate.

I. An Intertemporal Optimizing Model

A. *The Long-Run Welfare Cost of Taxation*

The welfare cost of taxation arises from the fact that people are induced to make their decisions according to relative prices that do not reflect the true choices technology and factor endowments make available. This is quite applicable to several types of choices: 1) choices among several goods at a point in time; 2) choices among the same good at different points in time; and 3) choices among different goods at different points in time.

Most of the existing analyses of the welfare cost of taxation take a static point of view according to which utility- and profit-maximizing individuals are confronted *at a point in time* with an exogenously imposed wedge between marginal rates of transformation and marginal rates of substitution.[2] This is an accepted procedure for short-run analysis. It is not, however, fully satisfactory from a long-run point of view and a concern exists about the necessity of introducing dynamic considerations in the analysis of the welfare cost of taxation. As Arnold Harberger puts it: "As long as we take our problem seriously, we must face up to a possible effect of taxation on the volume of savings and investment and thus the problem of incorporating a dynamic element in what would otherwise be a static model must be faced" (p. 58).

The same concern can be found much earlier in the literature and may even be the basis of John Stuart Mill's disatisfaction with the double taxation on savings implied by the income tax. More recently, Irving Fisher and Kaldor took Mill's point to further elaborate that an income tax distorts the savings-consumption choice, and thus has an effect on the path of capital accumulation. This argument *inter alia* leads Kaldor to propose the adoption of an expenditure tax as a perfectly neutral tax regarding the savings-consumption choice; hence, the path of capital accumulation.

In agreement with this concern, we want to recognize that from a dynamic point of view, the welfare cost arises from distortions of all three types of choices mentioned above. That is, in the long run the welfare cost arises not only from an inefficient use of given resources, but also from the fact that the amount of resources available at every point in time itself is nonoptimal. It is my purpose to analyze the total welfare effects of taxation over the whole lifetime of taxes which are assumed to be enforced for a period long enough to affect the factor endowments of the economy. In so doing I will formally show the dynamic neutrality of Kaldor's expenditure tax and the dynamic nonneutrality of the income tax. The starting point of the analysis must be to consider the capital stock as an endogenous variable subject to the influence of taxation.

If we consider the capital stock as an endogenous variable, it seems very convenient to use an aggregation that separates the production of I goods from the production of other goods (consumption goods, C) and makes clear whether the changes in taxation under consideration strike I goods or C goods. The aggregation used in the standard two sector model à la Hirofumi Uzawa seems to be appropriate for this purpose. The supply side of the model has linearly homogeneous production functions for both commodities.

$$(1) \quad I(t) = F_I(K_I(t), N_I(t)) = N_I(t) f_I(k_I(t))$$

$$(2) \quad C(t) = F_c(K_c(t), N_c(t)) = N_c(t) f_c(k_c(t))$$

---

[2] One exception is a paper by David Levhari and Eytan Sheshinski. They analyze the lifetime welfare cost imposed by an interest-income tax upon a single individual whose income consists of a return (at a constant-over-time rate) on his capital.

We also assume full employment of capital K and labor N at every point in time t.

$$K_I(t) + K_c(t) = K(t) \tag{3}$$

$$N_I(t) + N_c(t) = N(t) \tag{4}$$

Assuming no depreciation, the aggregate quantity of capital existing at any point in time is given by the accumulation of I goods which have been produced in the past; namely,

$$DK(t) = I(t) \tag{5}$$

where D operator denotes time derivative.

We also assume that labor grows at a constant rate n,

$$DN(t)/N(t) = n$$

Because in a two-sector model factor allocations and output levels are fully determined by the only relative price of the model p, and the capital-labor ratio k, the procedure we will follow consists of evaluating the tax-induced changes in the pairs (p, k) that the economy attains at every point in time. This is analogous to the concern in static analysis with the effect of a tax upon market equilibrium (i.e., how equilibrium quantity and price change in response to a change in taxation). Once we know how the path is distorted, we search for the welfare implications of these changes in the path. This is analogous to the static procedure of evaluating the welfare triangles, once it is known how the instantaneous market equilibrium is affected by a change in taxation.

The procedure will be illustrated with a simple, particular case. On the demand side of the model we will postulate the simplest aggregate utility function; namely, utility equals per head consumption, $q_c(t)$ $(\equiv C(t)/N(t))$

$$U(t) = q_c(t)$$

This is the simplest case and for this reason I want to use it for my present illustrative purpose.[3]

Following Uzawa, assume the economy behaves so as to

$$\text{Maximize} \int_0^\infty U(q_c(t))e^{-\delta t}dt$$

subject to the constraints (1) to (5), where δ is the discount rate by which future consumption is weighted against present consumption. Allocating Lagrange multipliers $p_I(t)$, $p_c(t)$, $r(t)$, $w(t)$, and $q(t)$ to the constraints (1) to (5), yields the following Euler equations

$$U'(t) - p_c(t) = 0 \tag{6}$$

$$q(t) - p_I(t) = 0 \tag{7}$$

$$p_c(t)\partial F_c/\partial K_c(t) - r(t) = 0 \tag{8}$$

$$p_I(t)\partial F_I/\partial K_I(t) - r(t) = 0 \tag{9}$$

$$p_c(t)\partial F_c/\partial N_c(t) - w(t) = 0 \tag{10}$$

$$p_I(t)\partial F_I/\partial N_I(t) - w(t) = 0 \tag{11}$$

$$r(t) - (n + \delta)q(t) + Dq(t) = 0 \tag{12}$$

The transversality condition is

$$\lim_{t\to\infty} e^{-\delta t}q(t)k(t) = 0$$

By writing equations (6) to (12) as equalities, we are here assuming that all solutions to these Euler equations lie in the interior of the feasible set. This assumption rules out specialization. Clearly, $p_c(t) = U'(t)$ is the price of C goods; $p_I(t)$, which is equal to $q(t)$ by (7), is the price of I goods; $r(t)$ is the competitive rental rate of capital (from (8) and (9)); and $w(t)$ is the competitive wage rate (from (10) and (11)). To describe the optimal path we take the two dynamic relationships of the model; namely, equations (5) and (12). Now rewrite equation (5) in per capita terms

---

[3] It has been shown by the author that the results to be obtained here also hold in a more general model in which $U''<0$ (and, consequently, the locus $Dp=0$ is not a horizontal line).

$$
\begin{aligned}
&(13) \quad & Dk(\mathrm{t}) &= q_I(\mathrm{t}) - nk(\mathrm{t}) \\
&\text{where} & k(\mathrm{t}) &= K(\mathrm{t})/N(\mathrm{t}) \\
& & q_I(\mathrm{t}) &= I(\mathrm{t})/N(\mathrm{t}) \\
& & &= \frac{k_c(\mathrm{t}) - k(\mathrm{t})}{k_c(\mathrm{t}) - k_I(\mathrm{t})} f_I(k_I(\mathrm{t}))
\end{aligned}
$$

From (8), (9), (10), and (11) we know that factor intensities in the nonspecialization region are functions of the relative price only. Choosing the consumption good as the numeraire, define $p(\mathrm{t})$, the relative price of investment goods in terms of consumption goods, as $p_I(\mathrm{t})/p_c(\mathrm{t})$. Then equation (13) becomes

$$(14) \quad Dk(\mathrm{t}) = q_I(p(\mathrm{t}), k(\mathrm{t})) - nk(\mathrm{t})$$

Equations (7), (9), and (12) imply

$$
\begin{aligned}
\frac{Dp_I(\mathrm{t})}{p_I(\mathrm{t})} &= (n + \delta) - f_I'(k_I(\mathrm{t})) \\
&= (n + \delta) - f_I'(k_I(p(\mathrm{t})))
\end{aligned}
$$

Given the particular utility function, $q_c(\mathrm{t}) = U(\mathrm{t})$, $U'(\mathrm{t}) = 1$ and we can write

$$(15) \quad \frac{Dp(\mathrm{t})}{p(\mathrm{t})} = (n + \delta) - f_I'(k_I(p(\mathrm{t})))$$

Equations (14) and (15) form a system of two differential equations in $p(\mathrm{t})$ and $k(\mathrm{t})$. If I goods are relatively labor intensive, the locus of (p, k) along which (14) is at rest is upward sloping. On the other hand, (15) is independent of k in the nonspecialization region; i.e., (15) is at rest for the value of p that makes $(n+\delta) - f_I'(k_I(p)) = 0$.

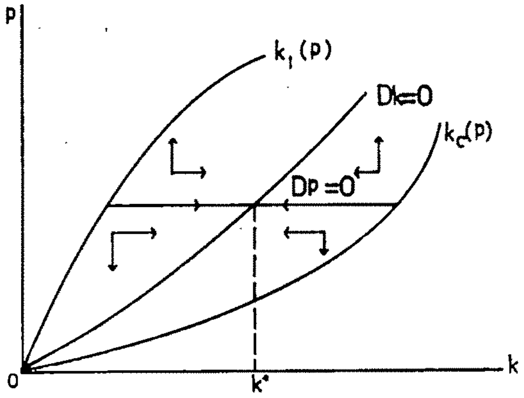

Figure 1. The Long-Run Equilibrium
(C goods are relatively capital intensive)

The rest point of the system (14) and (15) is shown in Figure 1, where k^* represents the steady-state capital-labor ratio. To keep the simplicity of this illustration, let us concentrate on the case in which I goods are relatively labor intensive. How do the time paths of k, $k(\mathrm{t})$, and of q_c, $q_c(\mathrm{t})$ look? To obtain these paths make use of the fact that p and therefore factor proportions in each sector are constant all along the path. Therefore, we can write both q_c and q_I as linear functions of k

$$q_I = \frac{f_I(k_I)}{k_I - k_c} k - \frac{f_I(k_I) k_c}{k_I - k_c}$$

$$(16) \quad q_c = -\frac{f_c(k_c)}{k_I - k_c} k + \frac{f_c(k_c) k_I}{k_I - k_c}$$

Substituting the first of the preceding two equations into (13) yields

$$Dk = \left(\frac{f_I}{k_I - k_c} - n \right) k - \frac{f_I k_c}{k_I - k_c}$$

Solving this differential equation for a given initial $k(0) = k_0$ gives

$$
\begin{aligned}
(17) \qquad k(\mathrm{t}) &= \left(k_0 - \frac{f_I k_c}{f_I - n(k_I - k_c)} \right) \\
&\quad \cdot \exp \left(\frac{f_I - n(k_I - k_c)}{k_I - k_c} \mathrm{t} \right) \\
&\quad + \frac{f_I k_c}{f_I - n(k_I - k_c)}
\end{aligned}
$$

$$(18) \quad \lim_{\mathrm{t} \to \infty} k(\mathrm{t}) = \frac{f_I k_c}{f_I - n(k_I - k_c)} = k^*$$

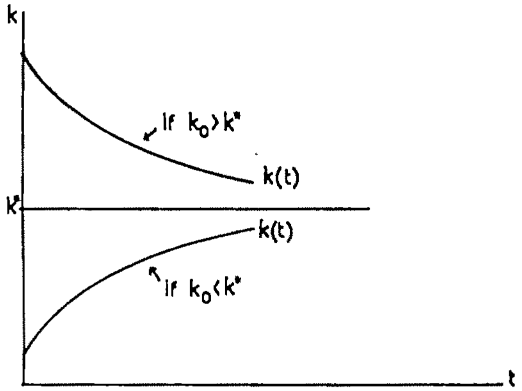

FIGURE 2. THE PATH OF CAPITAL ACCUMULATION

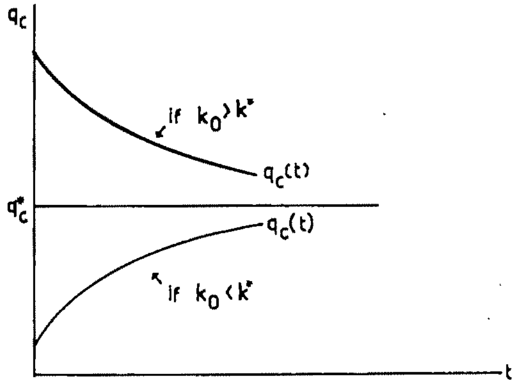

FIGURE 3. THE PATH OF CONSUMPTION

Therefore,

$$k(t) = (k_0 - k^*) \cdot \exp\left(\frac{f_I - n(k_I - k_c)}{k_I - k_c}\, t\right) + k^*$$

If $k_0 > k^*$, then k declines steadily toward k^* as t increases. If $k_0 < k^*$, then k increases steadily toward k^* as t increases. Substituting (17) into (16) gives the path of q_c, $q_c(t)$.

$$(19) \quad q_c(t) = \frac{f_c(k_I - k^*)}{k_I - k_c} - \frac{f_c(k_0 - k^*)}{k_I - k_c} \cdot \exp\left(\frac{f_I - n(k_I - k_c)}{k_I - k_c}\, t\right)$$

Equation (19) gives the optimal path of q_c, which starts at

$$(20) \quad q_c(0) = \frac{f_c(k_I - k_0)}{k_I - k_c}$$

and converges to

$$q_c^* = \frac{f_c(k_I - k^*)}{k_I - k_c}$$

These paths can be represented as in Figures 2 and 3.

Since we assume $U(t) = q_c(t)$, equation (19) is the path of utility. The discounted sum of all consumption per head along the optimal path gives the total utility of the whole program, W.

$$W = \int_0^\infty \frac{f_c(k_I - k^*)}{k_I - k_c} \exp(-\delta t)\, dt - \int_0^\infty \frac{f_c}{k_I - k_c}(k_0 - k^*) \cdot \exp t\left(\frac{f_I - n(k_I - k_c)}{k_I - k_c} - \delta\right) dt$$

Solving the above integral and making some algebraic manipulations we get

$$(21) \quad W = f_c \frac{f_I - (n + \delta)k_I + \delta k_0}{\delta(f_I - (n + \delta)(k_I - k_c))}$$

In the absence of any tax, $R = f_I' = n + \delta$; consequently, the total welfare of the program equals initial per head wealth: The present value of all future wages w plus the value of the initial capital labor ratio

$$W(\text{without tax}) = w/\delta + pk_0$$

B. *Effects of Taxation on the Time Path Followed by the Economy*[4]

In the preceding section we confronted the economy with the constraints implied by technology and factor endowments (equations (1) to (5)). In this section the situation in the presence of taxes will be described. The effect of taxes (as pointed out earlier) is to confront producers and consumers with different signals through the markets. Producers respond to a price different from the price to which the buyers respond. To make clear the effect of taxation on the signals perceived by producers and consumers, define $p_c^{\$}$ and $p_I^{\$}$ as the prices that producers receive in terms of an arbitrary numeraire (other than consumption goods, say "dollars"). Let the ratio $p_I^{\$}/p_c^{\$}$ be denoted by $\bar{p}$ (i.e., the relative price of I goods in terms of C goods as perceived by producers), and keep the notation p to denote the relative price as paid by buyers ($\bar{p}=p(1-T)$ for a tax on I and $\bar{p}=p/(1-T)$ for a tax on C). Disposable income of any individual in the model is the reward to his work $w(\bar{p})$, plus the reward to the capital owned by him $kr(\bar{p})$, plus whatever lump-sum transfer he receives from the government Z. (We follow the standard procedure in excess burden analysis of assuming that tax revenue is returned to the private sector as lump sum transfers.) When each individual decides how to spend his income, $w(\bar{p})+r(\bar{p})k+Z$, between present consumption and capital accumulation he faces a relative price p between q_I and q_c. That is, his decision may be posed as how to

---

[4] It is, of course, understood that all variables are functions of time t although the t is omitted for simplicity.

$$\text{Maximize} \int_0^\infty q_c(t)e^{-\delta t}dt$$

subject to one of the following constraints: For a tax on C at rate T, we have

$$(22) \quad \frac{p_c^{\$}}{1-T}q_c + p_I^{\$}q_I = w^{\$}(\bar{p}) + r^{\$}(\bar{p})k + Z^{\$}$$

where $p_c^{\$}$ is the price received by the producer and $p_c^{\$}/(1-T)$ is the price paid by the buyer, all expressed in dollars, and $w^{\$}(\bar{p}), r^{\$}(\bar{p})$, and $Z^{\$}$ have the same meaning as $w(\bar{p})$, $r(\bar{p})$, and Z above, except that they are now measured in dollars.

For a tax on I we get

$$(23) \quad p_c^{\$}q_c + \frac{p_I^{\$}}{1-T}q_I = w^{\$}(\bar{p}) + r^{\$}(\bar{p})k + Z^{\$}$$

For a tax on both C and I, i.e., an income tax, we obtain

$$(24) \quad \frac{p_c^{\$}}{1-T}q_c + \frac{p_I^{\$}}{1-T}q_I = w^{\$}(p) + r^{\$}(p)k + Z$$

Notice that in this last equation factor rewards are functions of p rather than $\bar{p}$. In the presence of an income tax the relative price between C and I faced by consumers equals the one faced by producers. After having made clear how the prices perceived by consumers and producers are distorted, we can now express our constraints in the more compact notation of relative prices only. From equation (22)

$$q_c + \frac{p_I^{\$}}{p_c^{\$}/1-T}q_I = \frac{w^{\$}(\bar{p})}{p_c^{\$}/1-T} + \frac{r^{\$}(\bar{p})}{p_c^{\$}/1-T}k + \frac{Z^{\$}}{p_c^{\$}/1-T}$$

Recalling that p is the relative price that a buyer faces in the market,

$$(25) \quad q_c + pq_I = (w(\bar{p}) + r(\bar{p})k + Z)(1-T)$$

Likewise, from (23)

$$(26) \quad q_c + pq_I = w(\bar{p}) + r(\bar{p})k + Z$$

And from (24)

$$(27) \quad q_c + pq_I = (w(p) + r(p)k + Z)(1-T)$$

1. *Consumption Tax*

In the presence of a tax on C goods, the problem faced by an optimizing individual is to maximize $\int_0^\infty q_c e^{-\delta t}dt$, subject to equation (25). The solution to this problem is

$$(28)\quad Dp/p = (1-T)r(\bar{p})/p - (n+\delta)$$
$$= R - (n+\delta)$$

Thus the individual will only be in equilibrium if the modified rate of time preference equals the net rate of return; i.e., the net rental he will receive per unit of capital divided by the price he paid for the capital good. The net rental he will receive is net in the sense of being determined by the net price (the price that producers receive, $\bar{p}$) and also in the sense that $(1-T)$ is taken away from it, since the individual consumes the rental. That is, when the individual considers the purchase of a machine, as opposed to immediate consumption, he deducts from the machine's rental the tax he will have to pay in order to consume these rentals.

Equation (28) defines the $Dp=0$ locus, which is a horizontal line as in Figure 1. The height of this line, however, is not the same as the height of the line in Figure 1 because in that case, p has to satisfy $r(p)/p=n+\delta$, whereas in the presence of a tax p has to satisfy $(1-T)r(\bar{p})/p=R=n+\delta$.

The equilibrium condition in our case is stated by equation (28); that is, by the equalization of the net rate of return $(1-T)r(\bar{p})/p$ with $n+\delta$. This is, of course, obviously true in the steady state, as can be seen by making equation (28) equal to zero. But since p is constant all along the optimal path, so is R. Then if $R=n+\delta$ in the steady state, R must be equal to $n+\delta$ all along the optimal path as well. The introduction of taxation affects the net rate of return without changing $n+\delta$. We must, therefore, know how the optimal path changes in the process of bringing back the net rate of return to equality with $n+\delta$. That is, we want to evaluate the horizontal shift of the $Dp=0$ locus due to a change in taxation. Using the fact that $E_{rT}=[T/(1-T)]E_{rp}$ and totally differentiating $(1-T)r(\bar{p})/p=n+\delta$, we get

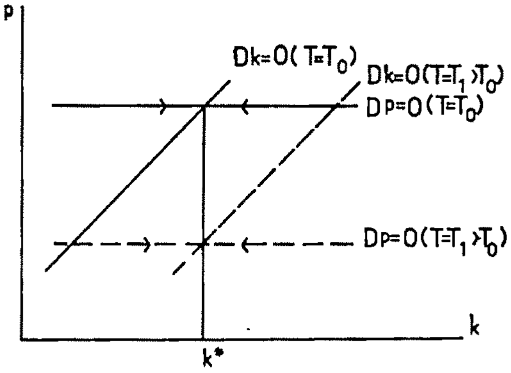

FIGURE 4. THE EFFECT OF A CONSUMPTION TAX ON THE LONG-RUN EQUILIBRIUM

$$\frac{T}{p}\frac{dp}{dT} = E_{pT} = -T/(1-T)$$

Moreover, assuming that $Dk=0$, and using the fact that $E_{q_I p}=[T/(1-T)]E_{q_I T}$ we get from $q_I(\bar{p}, k)=nk$ that

$$E_{pT} = -T/(1-T)$$

The effect of increasing a tax on C is depicted on Figure 4. Thus, an increase in the tax rate on C shifts both $Dk=0$ and $Dp=0$ schedules by the same distance, so that the steady-state capital-labor ratio k^* remains unchanged and p is reduced so as to keep $(1-T)r(\bar{p})/p=n+\delta$. The welfare implications of these shifts are discussed below.

2. *Tax on I Goods*

In the presence of a tax on I, the problem faced by an optimizing individual is to maximize $\int_0^\infty q_c e^{-\delta t}dt$, subject to equation (26). The solution to this problem is

$$(29)\quad r(\bar{p})/p = n+\delta$$

which states that the individual is in equilibrium only if the net rate of return equals the modified rate of time preference. To find out how this equilibrium condition is affected by changes in taxation, totally differentiate equation (29) to get

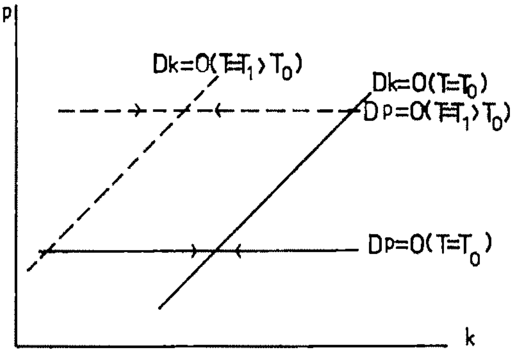

FIGURE 5. THE EFFECT OF AN INVESTMENT TAX ON THE LONG-RUN EQUILIBRIUM

$$E_{pT}\Big|_{Dp=0} = (T/1 - T)(E_{rp}/E_{rp} - 1)$$

Since $q_I(\bar{p}, k) = nk$, we get

$$E_{pT}\Big|_{Dk=0} = T/(1 - T)$$

The effect of increasing a tax on I is shown in Figure 5. Thus, an increase in the tax on I increases p and reduces $\bar{p}$, so as to keep $R = r(\bar{p})/p$ constant and equal to $n+\delta$.

How are the paths of k, $k(t)$, and of q_c, $q_c(t)$ affected by this change in taxation? From equations (18) and (20) calculate equations (30) and (31). Thus we have

$$\frac{dq_c(0)}{dT}\begin{cases} =0 & \text{for a tax on } C \\ >0 & \text{for a tax on } I \end{cases}$$

where

$$l_c(0) = \frac{N_c(0)}{N(0)} = \frac{q_c(0)}{f_c}$$

From $q_c^* = q_c(k^*, \bar{p})$ and $nk^* = q_I^* = q_I(k^*, \bar{p})$, we get

$$\text{(32)}\qquad \frac{dq_c^*}{d\bar{p}} = \frac{\partial q_c^*}{\partial k^*}\frac{dk^*}{d\bar{p}} + \frac{\partial q_c^*}{\partial \bar{p}}$$

$$= \frac{\partial q_c^*}{\partial k^*}\frac{(\partial q_c^*/\partial \bar{p})(1/p)}{(\partial q_I^*/\partial k^*) - n} + \frac{\partial q_c^*}{\partial \bar{p}}$$

$$= \frac{\partial q_c^*/\partial \bar{p}}{\partial q_I^*/\partial k^* - n}\left(\frac{r}{p} - n\right) > 0$$

That is, the steady-state level of per capita consumption moves in the same direction as the net (perceived by producers) relative price of capital $\bar{p}$. Therefore, q_c^* falls as a tax on I is increased.

It is clear from equation (30) that the steady-state capital-labor ratio k^* falls as we increase the tax rate on I, a result already observed in Figure 5. Since $\bar{p}$ falls at every time t as the tax on I is increased, q_I and therefore k will be smaller at every t. Therefore, we can show the effects of changes in taxation upon the path of k as in Figure 6. (Only the case $k_0 < k^*$ is shown. The opposite case follows *mutatis mutandi.*)

From equation (30) it can be seen that fixed proportions in both sectors will prevent any effect of taxation upon k^*. This is intuitively clear since in the presence of fixed proportions, and because of the full employment assumption, the economy will always be at a kink on the transformation curve and no changes in the composition of output are to be expected from "small" changes in taxation. With no

---

$$\text{(30)}\qquad \frac{dk^*}{dT} = \frac{\dfrac{dk_I}{dT}((k_c - k^*)f_I' + k^*n) + \dfrac{dk_c}{dT}(f_I - nk^*)}{f_I - n(k_I - k_c)} < 0$$

$$\text{(31)}\qquad \frac{dq_c(0)}{dT} = \left[\frac{dk_I}{dT}(f_c - q_c(0)) + \frac{dk_c}{dT}(l_c(0)(f_c - k_cf_c') + f_c'l_c(0)k_I)\right] \div [k_I - k_c]$$

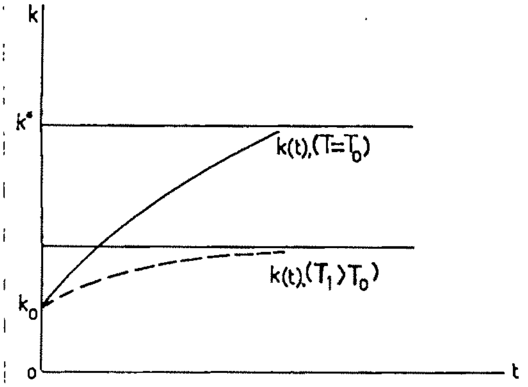

FIGURE 6. THE EFFECT OF AN INVESTMENT TAX ON THE PATH OF CAPITAL ACCUMULATION

change in the composition of output, the path of k remains unchanged.

Exactly the same comments apply to equation (31), which yields the change in per capita consumption at the time the tax rate changes, $t=0$. This result is also intuitively clear: as the tax on I is increased, the economy moves on the transformation curve towards more C being produced and consumed. This result together with equation (32) (which contains the effect of taxation upon steady-state per capita consumption q_c^*) allows the representation of the effect of taxation upon the path of q_c as in Figure 7.

Note that the path of q_c is twisted by a change in taxation. That is, an increase in the tax on I induces an increase in present consumption which implies less accumulation of capital, and results in less consumption in the future. These tax-induced modifications of the time path of consumption entail departures from the optimal path and thus a welfare cost which we discuss below.

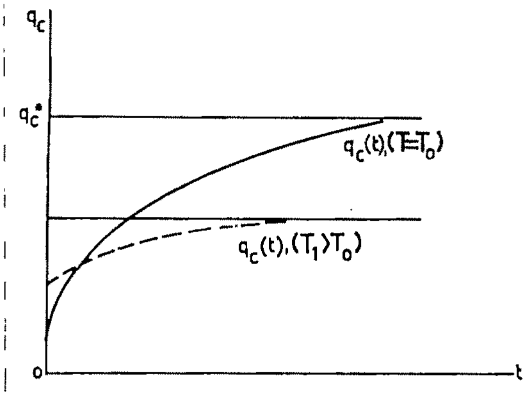

FIGURE 7. THE EFFECT OF AN INVESTMENT TAX ON THE PATH OF CONSUMPTION

3. *Income Tax*

In the presence of an income tax the problem faced by an optimizing individual is to maximize $\int_0^\infty q_c e^{-\delta t}dt$, subject to equation (27). The solution to this problem is

$$(33) \qquad (1 - T)r(p)/p = n + \delta$$

Which we totally differentiate with respect to p and T to get

$$E_{pT}\bigg|_{Dp=0} = (T/1 - T)(1/E_{rp} - 1) < 0$$

Equation (14) is not affected by income taxation, so that

$$E_{pT}\bigg|_{Dk=0} = 0$$

The final outcome is shown in Figure 8. Thus, an increase in the income tax rate reduces p so as to keep $(1-T)r(p)/p$ constant and equal to $n+\delta$. This reduction in

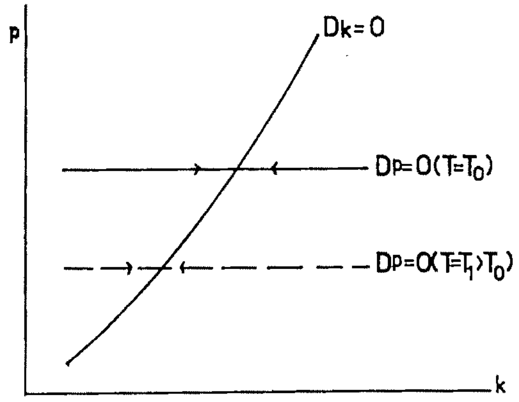

FIGURE 8. THE EFFECT OF AN INCOME TAX ON THE LONG-RUN EQUILIBRIUM

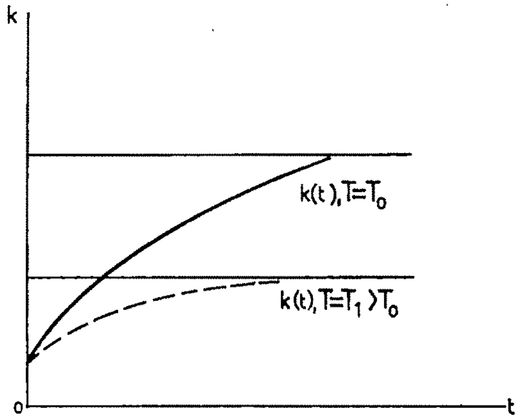

FIGURE 9. THE EFFECT OF AN INCOME TAX ON THE PATH OF CAPITAL ACCUMULATION

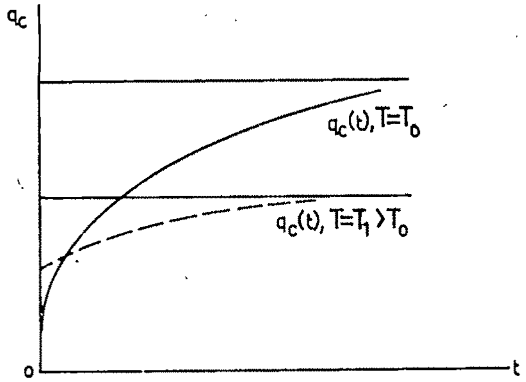

FIGURE 10. THE EFFECT OF AN INCOME TAX ON THE PATH OF CONSUMPTION

p implies (since p is now identical to $\bar{p}$) a fall in $\bar{p}$, which produces a reduction in q_I. This results in a lower k, a lower k^*, and a lower q_c^* (see equations (30) and (32)) as well as a greater $q_c(0)$ according to equation (31). Therefore, the paths of k and q_c are affected as shown above in Figures 9 and 10. The twist in the consumption path entails a welfare cost which we discuss next.

C. *Welfare Implications of Tax-Induced Changes in the Path*

1. *Consumption Tax*

Since a consumption tax will strike both present and future consumption, consumers face an unchanged relative price between present and future consumption. Therefore, their intertemporal maximizing behavior still consists of allocating their resources exactly as they would in the absence of taxation.

They cannot, however, buy future consumption as such. They can only buy investment goods in order to consume the rentals in the future. This fact brings in two effects: 1) the rental that an investment good is able to yield is itself a function of taxation (i.e., r depends on T, given p); and 2) the consumption of those rentals is taxed at rate T (unless the individual never consumes those rentals, but in such a case the purchase of the investment good becomes purposeless!). At a given p these two effects make the purchase of investment goods less attractive as T goes up. On the other hand, under the same circumstances the production of investment goods becomes more attractive ($\bar{p}$ goes up as T goes up, for a given p). There will, therefore, be an excess supply of I which will disappear as p falls. The fall in p necessary to restore equilibrium is such that $\bar{p}$ returns to its level prior to the change in taxation, so that $r(\bar{p})$ is kept unchanged. Such a fall in p leaves as the tax burden of purchasing an investment good only the tax on the consumption of the rentals (but the rentals themselves are unaffected).

Since this is also the tax burden of immediate consumption, no incentive arises to modify the allocation of any individual's resources between present and future consumption, so that present and future consumption will be demanded in the same proportion as before the change in taxation. A constant $\bar{p}$ implies that they will also be supplied in the same proportions as before the change in taxation and therefore there is neither excess demand nor excess supply at this lowered p and unchanged $\bar{p}$.

This is exactly the situation described in Figure 4. Since $\bar{p}$ is not affected by taxation the flow supply of and demand for investment goods and therefore Dk, q_c^*, and k^* are independent of taxation. Since the paths of q_c and k are undistorted, no welfare cost arises from this tax.

2. *Tax on I*

As depicted in Figure 7, an increase in the tax rate on I goods affects the intertemporal allocation of resources decreasing future and increasing present consumption. The total welfare cost of this distortion can be expressed as the change in W from equation (21).

Therefore, equation (21) becomes

$$\text{(34)}\quad W\,(\text{tax on } I) = \frac{w/\delta + pk_0 + Tpf_I/\delta}{1 + Tpf_I/f_c}$$

Now we can answer the question about the welfare implications of the tax-induced shifts of the optimal path. Take the general welfare indicator, equation (21), and differentiate with respect to the tax rate on I goods to get

$$\text{(35)}\quad \frac{1}{W}\,\frac{dW}{dT} = \frac{dk_c}{dT}\left(\frac{f_c'}{f_c} - \frac{(n+\delta)p}{f_c + Tpf_I}\right) + \frac{dk_I}{dT} \cdot \left(\frac{((n+\delta)k_c - \delta k_0)(f_I' - (n+\delta))}{(f_I - (n+\delta)k_I + \delta k_0)(f_c + Tpf_I)}\right) < 0$$

It can be seen from equation (35) that fixed proportions in both sectors will prevent the existence of any welfare cost of taxation. This is intuitively clear and follows from the fact that fixed proportions will prevent any effect of taxation upon the paths of k and q_c, as pointed out above. It can also be seen from this equation that a tax on C has no welfare cost, as already stated: One need only notice that both dk_c/dT and dk_I/dT are identically zero for a tax on C since such a tax does not change $\bar{p}$ and therefore cannot change either k_c or k_I.

3. *Income Tax*

Figure 10 shows the effect of the income tax on the path of q_c. It is analogous to the effect of a tax on I. The reason for this analogy is clear: both an income tax and a tax on I make future consumption more expensive relative to immediate consumption.

The effect of an income tax is not only analogous to the effect of a tax on I. They are also quantitatively equivalent. The reason for this is that the distortion in the path is exactly the same in both cases: as a consequence of an income tax the price received by producers falls, according to a total differentiation of (33), by $T/(1-T)(E_{rp}-1)$. As a consequence of a tax on I, the price paid by consumers rises according to total differentiation of (29), by $TE_{rp}/(1-T)(E_{rp}-1)$. Thus, the change in the price received by producers due to I tax is

$$\frac{T}{1-T}\left(\frac{E_{rp}}{E_{rp}-1} - 1\right).$$

which is equal to $T/(1-T)(E_{rp}-1)$. This is exactly the change in the price perceived by producers due to an income tax.

This numerical equivalence follows from the fact that the consumption tax is neutral. Therefore, the addition of it to a tax on I (to make up a tax on income) does not change the effect of the tax on I. They are, thus, the effects of an income tax as well.

An income tax at rate T and a tax on I at rate T have the same welfare cost. The tax revenue, however, will not be the same, an income tax has a wider base and then its revenue will be greater than the revenue of a tax on I at equal rates. Therefore, the welfare cost per dollar of tax revenue of an income tax is smaller than the welfare cost per dollar of tax revenue of an investment tax.

D. *Tax Equivalence*

It is interesting to note that the effects of taxes on the two goods in the model are not symmetric: A tax on I reduces $k(t)$ at every future t; a tax on C does not. A tax on I increases $q_c(0)$; a tax on C does not. Taxes on both C and I do not cancel each other out and thus have an effect on the economy although the relative price p is unaffected. These results may seem to conflict with the principle that only relative prices matter. There is, however, no conflict. Consumers are only concerned about consumption goods at different points in time (which are the only arguments entering their utility functions) and the principle that only relative prices matter fully applies to them. Thus, a tax on C which is kept forever leaves the relative prices of present and future consumption unchanged, implying no intertemporal allocative effect. A tax on I, on the other hand, makes the postponement of consumption (through the purchase of an investment good whose yield will be consumed) more expensive relative to immediate consumption. An income tax also makes the postponement of consumption more expensive relative to immediate consumption, even though both consumption and investment goods are taxed at the same rate (i.e., p is unaffected) because present consumption entails paying the tax only once, while future consumption entails paying a tax as the investment good is bought and again when its yield is consumed.

Since taxes on C and I are not symmetric, a tax (subsidy) on I is not equivalent to a subsidy (tax) on C: the former distorts the choice between present and future consumption while the latter does not. Thus a question arises as to what (if any) set of taxes and/or subsidies exactly duplicates the effects of another set of taxes and/or subsidies. To answer this question, it is convenient to use a very simple model. Assume a one-sector model in which the only commodity can be used for consumption or investment purposes. The economy is initially endowed with a quantity K_1 of such commodity. For simplicity assume no depreciation occurs. Keep the notation δ to represent the rate of time preference and also keep a simple utility function $U_t = C_t$, where C_t is the quantity consumed in period t.

To further simplify, assume a constant-over-time labor force which is inelastically supplied at each point in time. The economy is assumed to

$$\text{Maximize } (C_1 + C_2/(1+\delta) + C_3/(1+\delta)^2 + \ldots)$$

subject to

$$\begin{aligned} C_1 + (K_2 - K_1) &= f(K_1) \\ C_2 + (K_3 - K_2) &= f(K_2) \\ &\ldots \\ C_i + (K_{i+1} - K_i) &= f(K_i) \end{aligned}$$

where $f(K_i)$ is a neoclassical production function, namely,

$$f(K_i) = AK_i^a, \qquad A > 1,\ 0 < a < 1 \tag{36}$$

The solution to this problem is

$$f'(K_i) = \delta \tag{37}$$

which shows that the optimal stock of capital at each point in time is the one for which the marginal product of capital equals the rate of time preference.

From (36) and (37):

$$K_i = (aA/\delta)^{a/(1-a)}, \qquad i \geq 2$$

Therefore,

$$\begin{aligned} C_i &= A(aA/\delta)^{a/(1-a)}, \qquad i \geq 2 \\ C_1 &= AK_1^a - ((aA/\delta)^{1/(1-a)} - K_1) \end{aligned}$$

Assume now that a tax on investment at rate T is imposed in the first period, to be kept forever. The constraints of the problem now become

$$C_1 + (K_2 - K_1)(1 + T) = f(K_1) + Z_1$$
$$C_2 + (K_3 - K_2)(1 + T) = f(K_2) + Z_2$$
$$\dots$$
$$C_i + (K_{i+1} - K_i)(1 + T) = f(K_i) + Z_i$$

where Z_i represents the lump sum return of the tax proceeds to the private sector. The solution to the optimization problem subject to those new constraints is

$$f'(K_i) = (1 + T)\delta$$

Therefore,

$$(38) \quad K_i^T = (aA/(1 + T)\delta)^{1/(1-a)}, \quad i \geq 2$$

$$(39) \quad C_i^T = A(aA/(1 + T)\delta)^{a/(1-a)}, \quad i \geq 2$$

$$(40) \quad C_1^T = K_1^a - \left\{(aA/(1 + T)\delta)^{1/(1-a)} - K_1\right\}$$

The index T attached to the variables above denotes the optimal values of these variables in the presence of the tax.

The effect of an investment tax is to increase immediate consumption (i.e., $C_1^T > C_1$) and to reduce both the steady-state capital stock (i.e., $K_i^T < K_i$, $i \geq 2$) and future consumption (i.e., $C_i^T < C_i$, $i \geq 2$). These results confirm our earlier results.

Next assume a set of subsidies to consumption is imposed. Denote by X_t the rate of the subsidy at time t. In the presence of the subsidy the constraints of the problem become

$$\frac{C_1}{1 + X_1} + (K_2 - K_1) = f(K_1) - Z_1$$
$$\frac{C_2}{1 + X_2} + (K_3 - K_2) = f(K_2) - Z_2$$
$$\dots$$
$$\frac{C_i}{1 + X_i} + (K_{i+1} - K_i) = f(K_i) - Z_i$$

where Z_i represents a lump sum tax equal to the amount of the subsidy. The solution to the optimization problem subject to these new constraints is

$$(1 + X_{i-1})(1 + \delta) = (f'(K_i) + 1)(1 + X_i)$$

which reduces to equation (37) if $X_{i-1} = X_i$. This confirms the dynamic neutrality of a constant-over-time rate subsidy (or tax) on consumption.

Then

$$(1 + X_{i-1})\delta = (1 + X_i)f'(K_i) + X_i - X_{i-1}$$

Therefore we have optimal values for K_i, C_1, and C_i as shown in (41), (42), and (43). The index S attached to the variables denotes the optimal values of those variables in the presence of the subsidy. By comparing C_1^S, C_i^S for $1 \geq 2$ and K_i^S for $i \geq 2$ with C_1^T, C_i^T for $i \geq 2$ and K_i^T for $i \geq 2$, respectively, we find the sequence of X_i which yields the same paths of C and K as the investment tax at constant rate T.

$$(41) \quad K_i^S = \left(\frac{aA(1 + X_i)}{(1 + X_{i-1})\delta - (X_i - X_{i-1})}\right)^{1/(1-a)} \qquad i \geq 2$$

$$(42) \quad C_1^S = AK_1^a - \left(\left(\frac{aA(1 + X_2)}{(1 + X_1)\delta - (X_2 - X_1)}\right)^{1/(1-a)} - K_1\right)$$

$$(43) \quad C_i^S = A\left(\frac{aA(1 + X_i)}{(1 + X_{i-1})\delta - (X_i - X_{i-1})}\right)^{a/(1-a)} - \left(\left(\frac{aA(1 + X_{i+1})}{(1 + X_i)\delta - (X_{i+1} - X_i)}\right)^{1/(1-a)} - \left(\frac{aA(1 + X_i)}{(1 + X_{i-1})\delta - (X_i - X_{i-1})}\right)^{1/(1-a)}\right)$$

It can be seen from equations (38) and (41) that K_i^a and K_i^T are the same if and only if,

$$(1 + T)\delta = \frac{1 + X_{i-1}}{1 + X_i}\delta - \frac{X_i - X_{i-1}}{1 + X_i}$$

That is,

$$\frac{X_i - X_{i-1}}{1 + X_i} = -T\frac{\delta}{1 + \delta} \tag{44}$$

Thus a sequence of consumption subsidies at decreasing rates (i.e., $X_{i-1} > X_i$) that satisfies equation (44) has the same effect on the path of capital accumulation as an investment tax at a constant-over-time rate T. Equation (44) is also the necessary and sufficient condition for C_1^T to be equal to C_1^S: equations (40) and (42) are the same if, and only if, equation (44) is satisfied.

Equation (44) is also the necessary and sufficient condition for C_i^T $(i \geq 2)$ and C_i^S $(i \geq 2)$ to be the same: when $(X_i - X_{i-1})/(1 - X_i) = T(\delta/1 + \delta)$, the right-hand side of equation (43) becomes equal to

$$A(aA/(1 + T)\delta)^{a/(1-a)}$$

as in equation (39).

We then conclude that a sequence of consumption subsidies at a decreasing-over-time rate satisfying equation (44) yields the same paths of consumption and capital accumulation as an investment tax at a constant-over-time rate.

A Geometrical Exposition of Input-Output Analysis

By DANIEL A. GRAHAM*

A number of important theorems have been developed regarding the qualitative properties that input-output and related economic models must possess in order to be viable. That a number of apparently different notions of viability (for example, all industries can make profits, balanced growth is possible, any set of final demands can be produced) turn out to be equivalent, is one of the more important results. These theorems, normally expressed in the vernacular of the mathematician, have enjoyed only limited recognition, however, despite their proven usefulness and the ever increasing interest in such models. The strategy of this paper will be to exploit the purely geometrical nature of one condition for viability in order to expose the equivalence of seven other important conditions. It is hoped that this relatively simple geometrical exposition will not only tie the main mathematical results together but will also bring these results within the reach of a wider audience.

The input-output model is specified by the (semipositive) matrix of input coefficients[1]

$$A = [a_{ij}] = \begin{bmatrix} a_{11} & a_{12}, \dots, a_{1n} \\ a_{21} & a_{22}, \dots, a_{2n} \\ \cdot & \cdot \qquad\quad \cdot \\ \cdot & \cdot \qquad\quad \cdot \\ a_{n1} & a_{n2}, \dots, a_{nn} \end{bmatrix}$$

where a_{ij} denotes the amount of the ith good required as an input to produce each unit of the jth good. The jth column of A corresponds, therefore, to the input requirements of the jth industry (per unit of output). The gross output levels are given by the vector

$$x = (x_1 \quad x_2, \dots, x_n)'$$

where x_i denotes the gross output of the ith good. Notice, in this context, that the vector Ax represents the input requirements associated with gross output levels equal to x and, thus, the vector

$$x - Ax = (I - A)x$$

represents the net output levels corresponding to x.

A prime concern in input-output analysis is the question of whether or not a particular set of final demands can be satisfied. In other words, in what circumstances is the following "weak solvability" condition satisfied?[2]

1) Weak Solvability: $(I-A)x \geqq c$ has a solution $x \geqq 0$ for *some* set of final demands $c > 0$.

It is also of interest to determine the conditions under which any set of final demands could be satisfied.

---

* Associate professor of economics, Duke University. Financial support from the Ford Foundation-sponsored Duke University research project on input-output analysis is gratefully acknowledged. I am indebted to an anonymous referee for helpful comments on a previous draft of this paper.

[1] The matrix A is semipositive if every row and column is a semipositive vector. A semipositive vector is a vector composed of nonnegative elements, at least one of which is strictly positive. Since semipositive matrices form the basis of the von Neumann model and other linear economic models as well as the input-output model, the methods of this paper can be easily extended to more general circumstances.

[2] We employ the conventional vector notation that $a = b$ iff $a_i = b_i$ for all i, $a \geqq b$ iff $a_i \geqq b_i$ for all i, $a \geq b$ iff $a \geqq b$ and $a \neq b$, and $a > b$ iff $a_i > b_i$ for all i.

2) Strong Solvability: $(I-A)x=c$ has a solution $x\geqq 0$ for *any* $c\geqq 0$.

A related issue involves the question of whether or not there exist prices at which all industries could operate profitably.

3) Profitability: $p[I-A]>0$ has a solution $p>0$.

A final concern involves the dynamic specification of an input-output model that outputs of one period become the inputs of the next period, i.e.,

$$Ax_t \leqq x_{t-1}$$

denote the input constraints for production in period t. The issue in this context is to determine whether or not growth is possible.

4) Growth: $Ax_t \leqq x_{t-1}$, $x_t > x_{t-1}$ has a solution x_t, $x_{t-1} \geqq 0$.

The fact that these conditions take the form of restrictions upon the matrix A is obvious. The fact that these conditions are equivalent to one another and to any of the following additional conditions is less obvious.[3]

5) Hawkins-Simon: The leading principal minors of $[I-A]$ are all positive, i.e.,

$$\det(1-a_{11})>0,$$

$$\det\begin{bmatrix} 1-a_{11} & -a_{12} \\ -a_{21} & 1-a_{22} \end{bmatrix} > 0, \ldots,$$

$$\det[I-A]>0$$

6) Dominant Diagonal: The matrix $[I-A]$ has a dominant positive diagonal, i.e., there exist numbers (weights) $d_j>0$ such that

$$d_j(1-a_{jj}) > \sum_{i\neq j} d_i a_{ij}, \qquad j=1,\ldots,n$$

7) The dominant root of A is less than one.[4]

Condition 7) gives rise to interest in the dominant root of semipositive matrices. The most important theorems in this regard may be stated as follows:[5]

If A is a semipositive (indecomposable)[6] *matrix and if λ^* and x^* denote the dominant root and the associated characteristic vector, then:*[7]

$$\begin{array}{lll} \text{(a)} & \lambda^* \geqq 0 & (\lambda^* > 0) \\ \text{(b)} & x^* \geq 0 & (x^* > 0) \\ \text{(c)} & \dfrac{\partial \lambda^*}{\partial a_{ij}} \geqq 0 & \left(\dfrac{\partial \lambda^*}{\partial a_{ij}} > 0\right) \\ & & i,j=1,\ldots,n \\ \text{(d)} & [\lambda I - A]^{-1} \geq 0 & \textit{iff } \lambda > \lambda^* \\ & ([\lambda I - A]^{-1} > 0 & \textit{iff } \lambda > \lambda^*) \end{array}$$

(e) *x^* is not necessarily the only semipositive characteristic vector. (x^* is the only semipositive characteristic vector.)*

(f) $[\lambda I - A]$ *has all leading principal minors positive iff* $\lambda > \lambda^*$.

The purpose of this note is to explain geometrically conditions 1) through 7) and theorems (a) through (f). This explanation will be illustrated in the context of a two-good model ($n=2$) where the matrix A is indecomposable. The arguments can be immediately generalized to three goods ($n=3$) and offer considerable insights into the general case, however. The modifications that are necessary when A is decomposable require no significant changes in approach and will be obvious to the reader.

---

[3] For proofs of these propositions see Hukakane Nikaido.

[4] A number λ (possibly complex) and a vector x (possibly complex) are referred to as a characteristic root and vector, respectively, of the matrix A iff $Ax=\lambda x$. The dominant root is the root of largest absolute value (the square root of the sum of the squares of the real and imaginary parts of the complex root). In the case of a semipositive matrix this root happens to be real and nonnegative and the associated characteristic vector is real.

[5] These results are referred to as the Perron-Frobenius Theorems. See Edwin Burmeister and A. Rodney Dobell, pp. 437–40 for a compact statement of these and related results.

[6] A matrix is decomposable (indecomposable) if there exists (does not exist) a partition of the set of indices $\{1, 2, 3, \ldots, n\}$ into nonempty sets I and J such that $a_{ij}=0$ $i\in I, j\in J$. If such a partition exists it means that the industries in J can operate independently of the industries in I. If no such partition exists then every industry requires either directly or indirectly the output of every other industry.

[7] Parentheses enclose those results which depend upon A being indecomposable as well as semipositive.

The following result will be indispensable in this endeavor:[8] If a, $b \neq 0$ then $a \cdot b = |a|\,|b| \cos\theta$, where θ is the included angle between the vectors a and b. Thus:

$a \cdot b > 0$ iff a and b form an acute angle $(0 \leq \theta < 90°)$

$a \cdot b = 0$ iff a and b form a right angle $(\theta = 90°)$

$a \cdot b < 0$ iff a and b form an obtuse angle $(90° < \theta \leq 180°)$

The system that will be illustrated has the input coefficients matrix

$$A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

We will assume initially $A > 0$ and that a_{11}, $a_{22} < 1$ ($a_{12} = 0$ or $a_{21} = 0$ would correspond to A being decomposable and $a_{ii} < 1$ means that the input requirement of an industry for its own output is less than the industry's total output).

Let us begin by considering the columns of the matrix

$$[I - A] = \begin{bmatrix} 1 - a_{11} & -a_{12} \\ -a_{21} & 1 - a_{22} \end{bmatrix}$$

The first column has the sign pattern $(+-)$ and thus belongs to the fourth quadrant while the second column has the sign pattern $(-+)$ and thus belongs to the second quadrant. Beyond this observation there are two interesting possibilities: 1) the cone generated by the two column vectors contains *all* of the positive (first) quadrant, or 2) the cone generated by the two column vectors contains *none* of the positive quadrant.[9] The first possibility is illustrated in Figure 1 and the second in Figure 2 (the cone is depicted by the shaded area in both cases). In both illustrations, the first column $(I-A)_{\cdot 1}$ is labeled B_1 and the second column $(I-A)_{\cdot 2}$ is labeled B_2.

In Figure 1 the cone B_2OB_1 contains all of the positive quadrant. The only other possibilities are that B_2 lies in the extended line OB_1 and thus that the cone B_2OB_1 is simply this extended line (the case in which $[I-A]$ is singular) or that the cone B_2OB_1 contains the negative (third) quadrant (illustrated in Figure 2). There are simply no other possibilities for the two vectors: they either "bend" toward the positive quadrant or they do not bend at all or they bend toward the negative quadrant. If there were three goods, the analogous (three dimensional) cone would either contain the positive orthant (see Figure 3), be a plane or a line, or contain the negative orthant.[10] Similarly, with n goods the cone either contains the positive orthant, is a linear subspace,[11] or contains the negative orthant. Notice that in all cases the cone either contains *all* of the positive orthant or *none* of the positive orthant.

It can now be shown that conditions 1) through 7) are equivalent by arguing that each is equivalent to:

8) The cone generated by the columns of $(I-A)$ contains the positive orthant, i.e.,

---

[8] See any text in linear algebra, for example, G. Hadley: The scalar product of two vectors, a and b, is denoted by $a \cdot b = \sum_{i=1}^{n} a_i b_i$. The Euclidean norm of a vector b is denoted by $|b| = (\sum_{i=1}^{n} b_i^2)^{1/2}$.

[9] The cone generated by a set of vectors $B_1 \ldots B_m \in R^n$ is defined to be the set $\{y \in R^n \mid y = \sum_{i=1}^{m} \alpha_i B_i, \alpha_i \geqq 0\ i = 1, \ldots m\}$.

[10] The positive orthant is the set $\{y \in R^n \mid y > 0\}$. The negative orthant is the set $\{y \in R^n \mid y < 0\}$.

[11] A linear subspace is a set S that has the property that if $x_1, x_2 \in S$ then $\alpha_1 x_1 + \alpha_2 x_2 \in S$ for all $\alpha_1, \alpha_2 \in R$ (all real numbers α_1 and α_2).

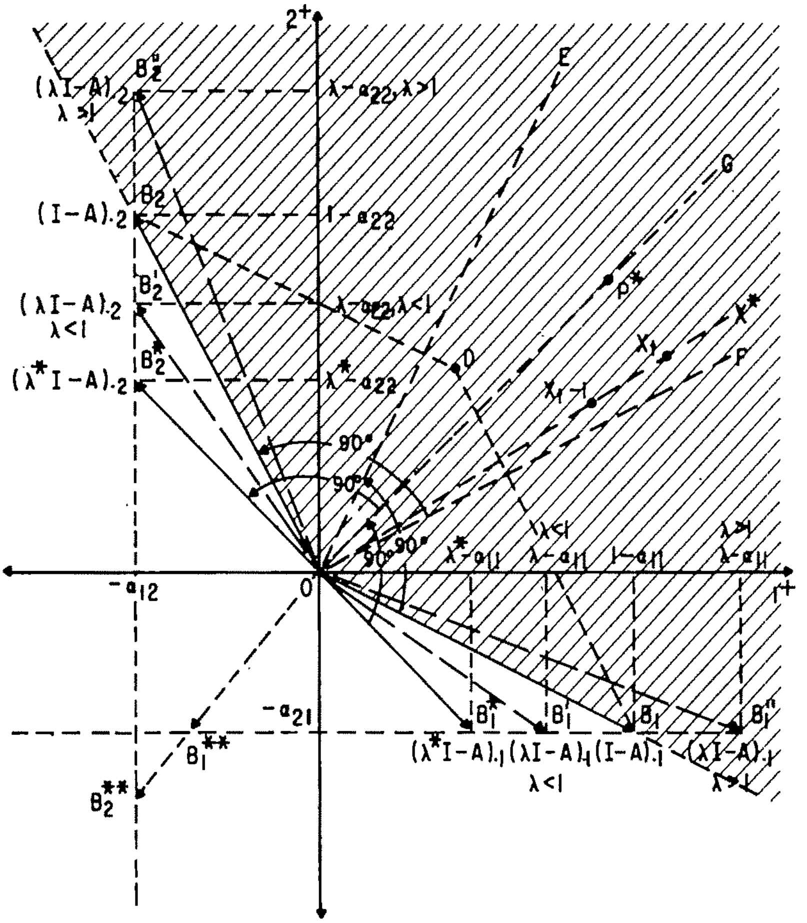

FIGURE 1. THE CASE OF VIABLE SOLUTIONS WITH TWO GOODS

$$\{y \in R^n \mid y = (I - A)x,\ x \geqq 0\} \supset \{y \in R^n \mid y > 0\}$$

Condition 1) states that the cone generated by $[I-A]$ contains at least one element from the positive orthant. Since this cone either contains all of the positive orthant or none of it, condition 1) is equivalent to condition 8). Condition 2) states that the cone generated by $(I-A)$ contains all of the nonnegative orthant (the positive orthant together with the positive axes) and is thus obviously equivalent to condition 8).

Condition 3) states that there exists a positive vector p that forms a strictly positive scalar product with every column of $[I-A]$. This simply means that p forms an acute angle with every column of $[I-A]$. To say that every column of $[I-A]$ forms an acute angle with a strictly positive vector is clearly equivalent, moreover, to the statement that the columns of $[I-A]$ bend toward the positive orthant or the statement that the cone generated by the columns of $[I-A]$ contains the positive orthant. Thus condition 3) is equivalent to condition 8). Notice in this regard that the interior of the cone *EOF* in Figure 1 represents the set of price

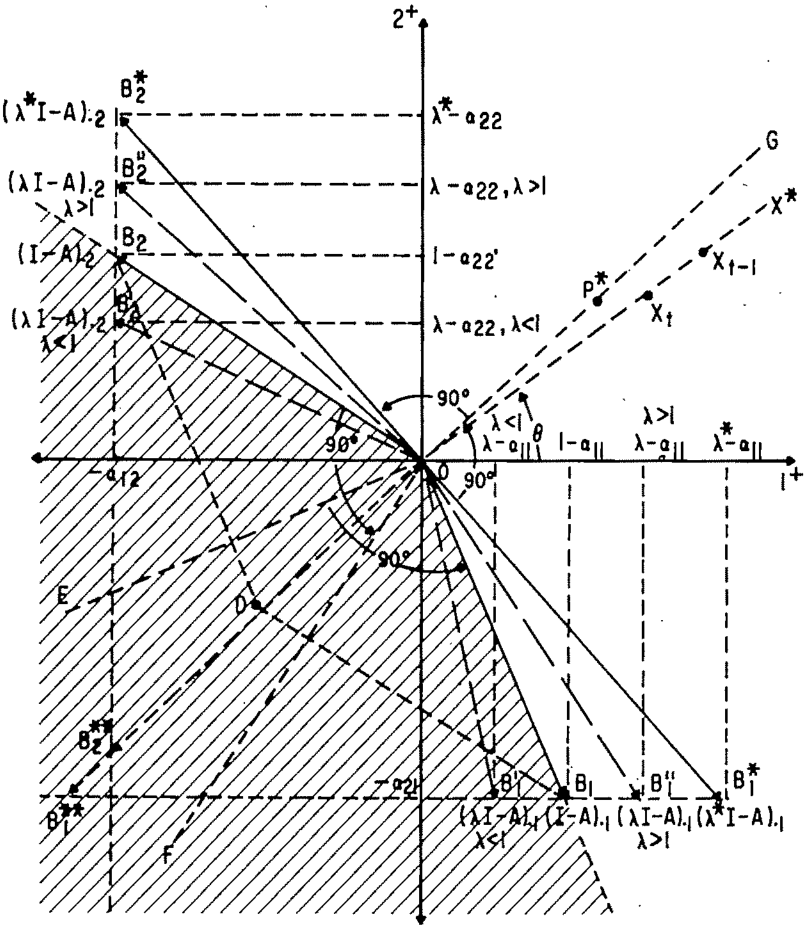

FIGURE 2. THE CASE OF NO VIABLE SOLUTIONS WITH TWO GOODS

vectors at which both industries could operate profitably. (The analogous cone *EOF* in Figure 2, on the other hand, contains only negative prices.)

Condition 4) states that there exist x_t, x_{t-1} such that $x_t > x_{t-1}$ and $Ax_t \leqq x_{t-1}$. If we define

$$c = x_t - x_{t-1} > 0$$

we may simplify this condition as follows:

$$x_{t-1} - Ax_t \geqq 0$$

$$x_{t-1} - A(x_{t-1} + c) \geqq 0$$

$$x_{t-1} - Ax_{t-1} \geqq Ac > 0$$

$$(I - A)x_{t-1} > 0$$

Condition 4) states, therefore, that the cone generated by the columns of $[I-A]$ contains an element from the positive orthant. Thus condition 4) is equivalent to condition 1) which has already been shown to be equivalent to condition 8).

Condition 5) is the most difficult to interpret. For the case of two goods ($n=2$) it requires that

$$\det (1 - a_{11}) > 0,$$

$$\det \begin{bmatrix} 1 - a_{11} & -a_{12} \\ -a_{21} & 1 - a_{22} \end{bmatrix}$$

$$= (1 - a_{11})(1 - a_{22}) - a_{12}a_{21} > 0$$

Notice that it is necessary for the second-order determinant to be positive that $(1-a_{22})$ be positive also. A moment's consideration reveals that if either $(1-a_{11})$ or $(1-a_{22})$ were negative the corresponding column of $(I-A)$ would lie in the negative (third) quadrant and it would be impossible for the cone generated by the columns of $[I-A]$ to contain the positive quadrant irrespective of the position of the other column. This reasoning is also correct for the case of three or more goods.

Sufficient conditions for higher order determinants to be positive are more troublesome. Routine calculation reveals, however, that the determinant of $[I-A]$ for the case of two goods is (except for sign) the area of the parallelogram determined by the two columns of $[I-A]$.[12] That is, in Figure 1 the determinant of $[I-A]$ is equal to the area of parallelogram B_1OB_2D and in Figure 2 the determinant of $[I-A]$ is equal to ***minus*** the area B_1OB_2D. The sign in each case depends upon whether the area is obtained by "sweeping" counterclockwise from B_1 to B_2 (positive sign) or by sweeping clockwise from B_1 to B_2 (negative sign).[13] Thus requiring that both determinants be positive is equivalent to requiring that the cone generated by the (two) columns of $[I-A]$ contain the positive quadrant.

The case of three goods is only slightly more difficult. Here the determinant of $[I-A]$ can be interpreted (except for sign) as the volume of the parallelepiped formed by the (three) columns of $[I-A]$.[14] (This parallelepiped is illustrated in Figure 3.) The second-order leading principal minor is moreover (except for sign) area of the parallelogram obtained by p jecting $(I-A)_{.1}0(I-A)_{.2}D$ onto the pla formed by the first and second coordin axes.

This second-order leading principal nor is positive if the direction of movem from $(I-A)_{.1}$ to $(I-A)_{.2}$ is countercloc wise in the plane formed by the first ar second coordinate axes.[15] If the first- a second-order leading principal minors a positive the sign of the determinant $[I-A]$ depends upon whether the dire tion of movement from $(I-A)_{.2}$ $(I-A)_{.3}$ is counterclockwise (positi sign) or clockwise (negative sign) in th plane formed by the second and thir coordinate axes.

The three goods case with all leading principal minors positive is illustrated in Figure 3. That the first, second, and third-order leading principal minors are positive is illustrated, respectively, by the following observations: $(1-a_{11})$ is positive, the direction of sweep is counterclockwise from $(I-A)_{.1}$ to $(I-A)_{.2}$, and the directions of sweep from $(I-A)_{.1}$ to $(I-A)_{.2}$ and from $(I-A)_{.2}$ to $(I-A)_{.3}$ are both counterclockwise.[16] These conditions are clearly equivalent to the statement that the cone generated by $[I-A]$ contains the positive orthant.[17]

---

[12] If $[I-A]$ were singular, the parallelogram would degenerate (collapse) into a line segment which has zero area.

[13] The order "B_1 to B_2" is crucial. Recall that switching columns changes the sign of the determinant.

[14] If $[I-A]$ were singular the parallelepiped would degenerate (collapse) into a parallelogram which has zero volume. See Michael Spivak, p. 83, for a general discussion of the determinant as an "oriented" volume.

[15] There is a simple "rule of thumb" for determining the direction of counterclockwise sweep. Point the thumb of your *right* hand along the positive direction of one axis and the fingers curl in the direction of counterclockwise sweep (positive orientation) for movements in the perpendicular plane.

[16] The sign of the determinant of $[I-A]$ is determined in general by interchanging columns of $[I-A]$ until the resulting matrix has a ***normal orientation*** (until every column lies in the direction of counterclockwise sweep from the preceding column). If the number of required "switches" is odd, then the sign of the original determinant is negative; otherwise, the sign is positive. Note that in Figure 2 $[I-A]$ has a normal orientation to begin with and thus requires zero switches.

[17] It should be noted that if the *leading* principal minors are all positive, then *all* principal minors must be positive. In Figure 2, for example, the remaining

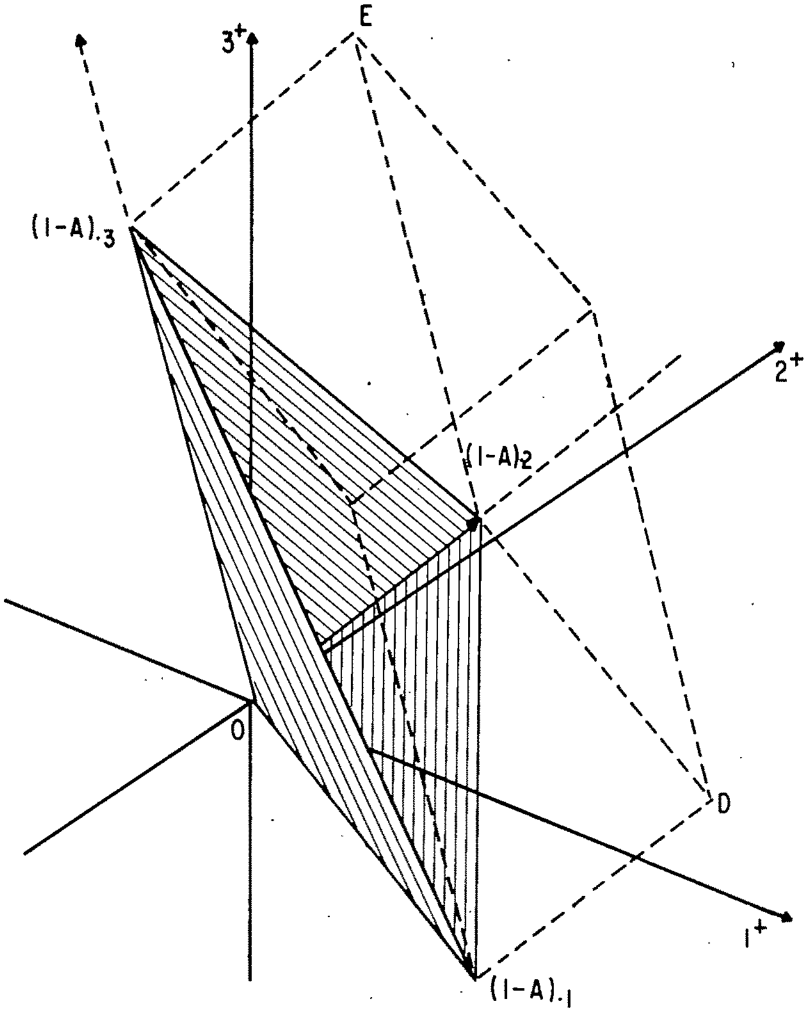

FIGURE 3. THE VIABLE SOLUTIONS CASE WITH THREE GOODS

Similar reasoning (with hyper-parallelepipeds) would establish the same result for an arbitrary number of goods and we may conclude that condition 5) is equivalent to condition 8).

Condition 6) states that there exists a vector

$$d = (d_1, \ldots, d_n) > 0$$

such that $d(I-A)>0$.

This condition is obviously equivalent to condition 3) which has already been discussed.

Condition 7) requires that the largest real root of A be less than one. To see this, first consider the case of two goods illustrated in Figure 1. The dominant root is

---

irst-order principal minors $(1-a_{22})$ and $(1-a_{33})$ must be positive as well as the second-order principal minors ormed by the second and third rows and columns and by the first and third rows and columns of $[I-A]$. The only trick in seeing this is to realize that in the last case he relevant sweep is from the third column to the first ather than from the first to the third. (The column that "preceeds" the first column in the cyclic order 1 2 3 1 . . . is the third).

the largest real number λ such that[18]

$$\det\begin{bmatrix}\lambda - a_{11} & -a_{12}\\ -a_{21} & \lambda - a_{22}\end{bmatrix} = 0$$

Notice that for $\lambda=1$ the determinant is equal to the area B_1OB_2D (in Figure 1) which is certainly not zero. It cannot be the case, therefore, that $\lambda=1$ is the dominant root.

Suppose now that we increase the "trial" value of λ to some value greater than one. This has the effect of bending the columns of $[\lambda I-A]$ further toward the positive quadrant and is illustrated in Figure 1 by the shifts from OB_1 to OB_1'' and from OB_2 to OB_2''. It is apparent that further increasing the trial value of λ will never make the determinant of $[\lambda I-A]$ equal to zero. The only case in which the determinant is zero occurs when both columns of $[\lambda I-A]$ lie in the same line (when the parallelogram collapses into a line segment). Increasing λ above 1 in Figure 1 simply bends these columns the wrong way.

Since any value of λ above one cannot be the dominant root, consider the effect of reducing λ below one. This has the effect of bending the columns of $[\lambda I-A]$ away from the positive quadrant and toward the negative quadrant and is illustrated by the shifts from OB_1 to OB_1' and from OB_2 to OB_2'. In fact, when λ is zero both columns of $[\lambda I-A]$ belong to the negative quadrant. It must be the case, therefore, that at some value of λ between one and zero the columns of $[\lambda I-A]$ cease to bend toward the positive quadrant and begin to bend toward the negative quadrant. At this point the columns of $[\lambda I-A]$ lie in the same line—$B_1^*OB_2^*$ in Figure 1. This value of λ is, of course, the dominant root and is denoted by λ^*. That is, λ^* appears at the point where the dominant diagonal vanishes.

Similar reasoning applied to Figure 2 leads to the conclusion that the dominant root must be greater than one when the cone contains the negative quadrant. The only other possibility, that $[I-A]$ is singular, corresponds to a dominant root equal to one. It is clear, therefore, that in the case of two goods the dominant root of A being less than one is equivalent to the cone generated by the columns of $[I-A]$ containing the positive quadrant.

For the case of three goods the reasoning is quite analogous. Here the problem is to choose λ so that the columns of $[\lambda I-A]$ lie in a plane. If the cone generated by the columns of $(I-A)$ contains the positive orthant, we must choose λ less than one in order to bend these columns away from the positive orthant and toward the negative orthant (see Figure 3). If the columns of $[I-A]$ generate a plane, then $[I-A]$ is singular and the dominant root is one. Lastly, if the columns of $[I-A]$ generate a cone which contains the negative orthant, then we must choose λ greater than one in order to bend these columns away from the negative orthant and toward the positive orthant. It is clear that this reasoning holds for an arbitrary number of goods and we may conclude that condition 7) is equivalent to condition 8).

An indirect implication of the above analysis is that the dominant root is nonnegative in *all* cases—Theorem (a). This can be seen as follows. For *any* negative λ the columns of $[\lambda I-A]$ belong to the nonpositive orthant.[19] On the other hand, by making λ sufficiently positive $[\lambda I-A]$ can be made to generate a cone which contains the positive orthant (each column of $\lambda I-A]$ approaches the respective positive coordinate axis as λ becomes larger and larger). There must exist a real characteristic root, therefore, between the negative and positive values of λ (which corresponds to the point at which the columns of $[\lambda I-A]$ bend neither toward the negative nor the positive orthants). Since this is true for any negative λ this root must be nonnegative. That is, there must exist λ^* greater than or equal to zero which satisfies these conditions.[20]

---

[18] λ is a solution of $Ax=\lambda x$ iff det $[\lambda I-A]=0$. See Hadley.

[19] The nonpositive orthant is the set $\{y\in R^n \mid y\leq 0\}$.

Notice that the columns of $[\lambda^* I-A]$ generate a degenerate or flat cone (a linear subspace). (This cone is illustrated by the infinite line through $B_2^*OB_1^*$ in Figure 1 or Figure 2.) The subset of this cone that would be obtained by considering only those nonnegative weights for the columns of $[\lambda^* I-A]$ that sum to one, i.e.,

$$\left\{y \mid y = \sum_{i=1}^{n} \alpha_i(\lambda^* I - A)_{\cdot i}, \quad \alpha_i \geqq 0, \ \sum_{i=1}^{n} \alpha_i = 1\right\}$$

is a convex polyhedral set whose vertices are formed by the columns of $[\lambda^* I-A]$ and which contains the origin. (This subset is illustrated by the line segment $B_1^*OB_2^*$ in Figure 1 or Figure 2 and would be a triangle passing through the origin in Figure 3.) That set of weights x_i^* which generates the origin (causes the sum of the weighted columns to be the origin) is a semipositive vector which satisfies

$$\sum_{i=1}^{n} x_i^*(\lambda^* I - A)_{\cdot i} = 0$$

$$(\lambda^* I - A)x^* = 0$$

$$Ax^* = \lambda^* x^*$$

and is thus the semipositive characteristic vector associated with the dominant root —Theorem (b).[21]

Theorem (c) follows from the fact that increasing *any* element of A either has no effect upon the (degenerate) cone generated by the columns of $[\lambda^* I-A]$ (possible only if A is decomposable) or it causes these columns to bend toward the negative orthant. For example, increasing either a_{11} or a_{21} in Figure 1 or Figure 2 rotates the first column of $(\lambda^* I-A)$ toward the negative quadrant. To bend these columns back toward the positive orthant (to obtain the dominant root of the new matrix) requires, therefore, increasing λ above the value of the original dominant root.

Theorems (d) and (f) both involve the fact that increasing λ above λ^* causes the columns of $[\lambda I-A]$ to bend toward the positive orthant. This means that λ being greater than λ^* is equivalent to the cone generated by the columns of $[\lambda I-A]$ containing the positive orthant. The discussion of condition 5) revealed, however, that the latter condition is necessary and sufficient for all leading principal minors of $[\lambda I-A]$ to be positive. Thus λ being greater than λ^* is equivalent to all leading principal minors of $[\lambda I-A]$ being positive —Theorem (f).

Theorem (d) says, in essence, that the inverse of $[\lambda I-A]$ is semipositive if and only if the cone generated by the columns of $[\lambda I-A]$ contains the positive orthant. To see this, let us construct the inverse of such a matrix. Notice that in Figure 1 the columns of $[I-A]$ generate a cone which contains the positive orthant. We may determine the rows of $[I-A]^{-1}$ by the following method. The fact that

$$[I - A]^{-1}[I - A] = I$$

Means that the first *row* of $[I-A]^{-1}$ must form an acute angle with the first ***column*** of $[I-A]$ (the product of these vectors must be one) and a right angle with the second *column* of $[I-A]$ (the product of these vectors must be zero). The first *row* of $[I-A]^{-1}$ must lie, therefore, somewhere along the extended line OF in Figure 1.

---

[20] The fact that λ^* is strictly positive when A is indecomposable is suggested by Figures 1, 2, and 3. For λ^* actually to be zero it is necessary that A be decomposable and singular.

[21] In Figure 1, notice that B_1^* and $(|B_1^*|/|B_2^*|)B_2^*$ have the same length. Thus $B_1^*+(|B_1^*|/|B_2^*|)B_2^*=0$ and $x^*=(1, |B_1^*|/|B_2^*|)>0$.

Similar reasoning reveals that the second row of $[I-A]^{-1}$ must lie along OE. Notice that this inverse matrix must be positive (or, perhaps, semipositive if A were decomposable).[22]

For an arbitrary number of goods one obtains a *row* of $[\lambda I-A]^{-1}$ by finding a vector that forms a zero scalar product (a right angle) with all *columns* of $[\lambda I-A]$ save one and a positive scalar product (an acute angle) with that one. Thus every row of the inverse must form a nonnegative scalar product (a nonobtuse angle) with every vector in the cone spanned by the columns of $[\lambda I-A]$. Since the cone spanned by the columns of $[\lambda I-A]$ contains the semipositive orthant if and only if λ is greater than λ^*, it follows that *every* row of the inverse must form a nonnegative scalar product (a nonobtuse angle) with every semipositive vector—that every row of the inverse is semipositive—if and only if λ is greater than λ^*. Thus for any number of goods, $[\lambda I-A]^{-1}$ being semipositive is equivalent to λ being greater than λ^*—Theorem (d).

To gain insight into the issue of decomposability consider the case in which the columns of $[I-A]$ span the positive orthant. The fact that

$$x = [I - A]^{-1}c$$

where x is the vector of gross output levels required to satisfy the vector of final demands c, means that

$$\frac{\partial x_i}{\partial c_j} = [I - A]_{ij}^{-1} \qquad i, j = 1, \ldots, n$$

may be interpreted as the increase in the gross output of the ith industry required to satisfy an increment in the final demand for the jth good. Now, if A is decomposable then there exists a partition of $\{1, 2, 3, \ldots, n\}$ into nonempty sets I and J such that[23] $a_{ij}=0$, $i\in I, j\in J$. This means that the columns of $[I-A]$ corresponding to the indices in J have zeros in the rows corresponding to the indices in I or simply that the J columns of $[I-A]$ lie in a linear subspace formed by the J positive coordinate axes. The I rows of $[I-A]^{-1}$ must be perpendicular (orthogonal) to each of the J columns of $[I-A]$, moreover. This means that the I rows of $[I-A]^{-1}$ must belong to the linear subspace formed by the I coordinate axes or that the I rows of $[I-A]^{-1}$ must have zeros in the columns corresponding to the indices in J. Thus

$$[I - A]_{ij}^{-1} = 0 \qquad i \in I, j \in J$$

and no change is required in the gross outputs of any of the I industries to increase final output in any of the J industries.

An example should clarify this. Consider the case of three goods where $[I-A]$ has the sign pattern:

$$\begin{bmatrix} + & - & - \\ - & + & - \\ 0 & 0 & + \end{bmatrix}$$

Clearly A is decomposable and $I=\{3\}$, $J=\{1, 2\}$ form the required partition. Notice that the first and second columns (the J columns) of $[I-A]$ lie in the plane (the linear subspace) formed by the first and second coordinate axes. For the third row of $[I-A]^{-1}$ to be perpendicular to both the first and second columns of $[I-A]$ it must be perpendicular to the plane determined by the first and second coordinate axes. The only possibility is that the third row (the I rows) of $[I-A]^{-1}$ must lie along the third coordinate axis

---

[22] If a_{21} were zero, for example, the first column of $[I-A]$ would lie along the positive first axis and the second row of $[I-A]^{-1}$ would lie along the positive second axis (and the lower left-hand corner of the inverse is zero). The partition of $\{1, 2\}$ is given in this case by $I=\{2\}$, $J=\{1\}$.

[23] Recall that I and J partition $\{1, 2, \ldots n\}$ iff $I\cap J=\phi$ and $I\cup J=\{1, 2, \ldots n\}$.

(the linear subspace formed by the I coordinate axes). This third row must, therefore, have zeros in the first and second places, i.e.,

$$[I - A]^{-1}_{31} = [I - A]^{-1}_{32} = 0$$

Theorem (e) requires some consideration of the other characteristic roots and vectors of A.[24] For the case of two goods illustrated in Figure 1 or Figure 2, the other root corresponds to the point at which $(\lambda I-A)_{\cdot 1}$ and $(\lambda I-A)_{\cdot 2}$ "cross" in the negative quadrant. This crossing must occur since $(\lambda I-A)_{\cdot 1}$ rotates clockwise through the negative quadrant toward the negative first axis as λ becomes smaller and smaller (more and more negative) and $(\lambda I-A)_{\cdot 2}$ rotates counterclockwise through the negative quadrant toward the negative second axis as λ becomes smaller and smaller. This crossing is illustrated by the vectors B_1^{**} and B_2^{**} in Figures 1 and 2. Notice that the characteristic vector corresponding to this root (the weights which make the columns B_1^{**} and B_2^{**} sum to the origin) cannot be semipositive since the origin does not belong to the line segment $B_1^{**}B_2^{**}$.

The case of three goods is quite similar. As λ becomes smaller and smaller, $(\lambda I-A)_{\cdot 1}$ (in Figure 3) rotates through the negative orthant toward the negative first axis, $(\lambda I-A)_{\cdot 2}$ rotates through the negative orthant toward the negative second axis, and $(\lambda I-A)_{\cdot 3}$ rotates through the negative orthant toward the negative third axis. Either there are two crossings of the type that one vector crosses the plane determined by the other two (the other two roots are real and distinct), or one vector coincides with the plane determined by the other two but does not actually cross it (two repeated real roots), or there are no crossings at all (two conjugate complex roots).[25] Any other real characteristic roots and vectors must correspond, therefore, to real crossings in the negative orthant. This means that the convex polyhedral set whose vertices are determined by the columns of $[\lambda I-A]$ (when evaluated at any other real root) cannot contain the origin. Any other real characteristic vector (the weights which make these columns sum to the origin) cannot, therefore, be semipositive. This reasoning holds for an arbitrary number of goods and we may conclude that x^* is the only semipositive characteristic vector—Theorem (e).

It should be noted in passing that λ^* and x^* have an economic interpretation. The search for balanced growth

$$x_t = \sigma x_{t-1}$$

with full employment

$$Ax_t = x_{t-1}$$

leads to the realization that $\sigma = 1/\lambda^*$ is the maximum balanced growth factor and x^* represents the balanced growth proportions. This means that $1/\lambda^* - 1$ can be regarded as the maximum (percentage) growth rate.

Consider, alternatively, the problem of determining the profit rate of the jth industry when prices are given by the (row) vector p. This profit rate is obtained by finding the discount rate, r, which makes the present value of receipts equal to the present value of production costs, i.e., the solution r to

$$p_j/(1 + r) - pA_{\cdot j} = 0$$

One naturally wonders if there exists an equilibrium vector of prices such that the profit rate is the same in all industries.

---

[24] There are a total of n (not necessarily distinct) characteristic roots and vectors of A. See Hadley.

[25] The latter possibility is due to the fact that the plane formed by any two vectors rotates as it sweeps through the negative orthant. It is therefore possible for this plane to "roll over" the other vector without ever actually crossing it.

That is, is there a set of prices p and a common profit rate r that satisfies

$$p/(1+r) - pA = 0$$

or, more simply,

$$p[1/(1+r)I - A] = 0$$

Clearly, $1/(1+r)=\lambda^*$ or $r=1/\lambda^*-1$ is the required common profit rate and $p=p^*$ (p^* is the characteristic *row* vector associated with the dominant root λ^*) is the required equilibrium price vector.

The vector p^* can be obtained geometrically by noticing that p^* must form a right angle with every column of $[\lambda^* I - A]$. For the case of two goods illustrated in Figure 1 or Figure 2, p^* must lie along line OG. Notice that p^* is positive in this case and that in general the same propositions can be established for this dominant row vector as were established for the dominant column vector x^*.

Finally notice that if λ^* is less than one, the maximum growth and profit rate, $1/\lambda^*-1$, is positive while if λ^* is greater than one, the maximum growth and profit rate is negative (see Figures 1 and 2).

Toward an Analysis of Postdisaster Cooperation

By Louis De Alessi*

There is evidence that, in the period immediately following a disaster, cooperative behavior increases.[1] Individuals apparently become more generous toward each other, offering goods and services at prices below those they could have obtained under the existing time-dated pattern of current and expected demand, and supply conditions. Thus, for example, the prices of such things as shelter and "emergency" foods often do not increase enough to clear the market, and the allocation of these and other goods is marked by a variety of formal and informal nonprice rationing schemes.[2]

A number of apparently conflicting hypotheses have been offered to explain this behavior. Accordingly, it seems useful to reexamine the problem and to place current contributions in their proper perspective.

Section I contains a summary of the arguments regarding whether disasters occasion a shift in individual utility functions toward more charity, as suggested by Douglas Dacy and Howard Kunreuther, or simply a decrease in the price of charity, as suggested by the author. Section II contains a review of Jack Hirshleifer's addendum that some postdisaster cooperation is due to alliance activities.[3] Section III contains a critique of Christopher Douty's attempt, based upon the alliance hypothesis, to rule out utility interdependence entirely and to explain postdisaster altruism essentially in terms of informal insurance arrangements. The range of application of the various hypotheses is examined further in Section IV, and Section V contains a few concluding remarks.

I. Utility Interdependence

Dacy and Kunreuther, in studying the aftermath of the Alaskan earthquake of 1964, were struck by the apparent increase in cooperative behavior. Having noted that other disasters had given rise to similar results, they conjectured that disasters yield short-run structural changes in individual utility functions toward more "community feeling." Individuals presumably derive utility from increases in the welfare of others,[4] and respond to the suffering and distress occasioned by a disaster by attaching greater weights to the welfare of the victims. Utility functions thus shift, and individuals behave with greater charity toward the victims. In due course, as the emergency wanes, utility functions recede toward their original positions.

* Professor of economics, George Washington University. I am indebted to the National Science Foundation for financial assistance and to Jack Hirshleifer, Douglas W. Webbink, and an anonymous referee for helpful comments.

[1] A disaster is defined as the sudden destruction of physical assets. Charity is defined as the intentional transfer of resources below their market prices for the purpose of making the recipients better off, as the donors see it, and is associated with utility interdependence. Cooperation is defined as charitable and seemingly charitable behavior (e.g., it includes wealth-maximizing business "gifts") and is used synonymously with altruism; thus, it excludes normal market interactions which in a broader context are a prime example of cooperative activity.

[2] G. Sjoberg, Douglas Dacy and Howard Kunreuther, Jack Hirshleifer, Christopher Douty, and the author, among others, discuss some of the pertinent evidence and note additional sources of information.

[3] A few words regarding the actual chronology of these contributions may be useful to readers puzzled by the apparent inconsistency of the publication dates shown. The study by Dacy and Kunreuther (1969) first appeared during 1966–67 in a series of Internal Notes, approved for external circulation, published by the Institute for Defense Analyses, Arlington, Virginia. The two papers by the author (1967, 1968) were drafted during the second half of 1966 as a result of several enjoyable conversations with Dacy and Kunreuther. One of the papers (1968) initially appeared in 1966 as an Internal Note, approved for external circulation, published by the Institute for Defense Analyses. Hirshleifer footnoted most of this material in his paper (1967), which he circulated privately.

I have argued that a shift in utility functions is not necessary to explain the behavior observed. If individual utility functions are initially interdependent, then a disaster lowers the welfare of the victims and enables donors to obtain more utility from any given gift.[5] The search and information costs of finding worthy recipients (as the donors see it) also decrease, and the opportunity to make others better off expands dramatically. In effect, a disaster lowers the price of charity. Individuals predictably engage in more charitable behavior,[6] reallocating some of their resources from other activities (including other charities) to the relief of disaster victims until each donor's utility-maximizing equilibrium is restored.[7] Since a shift in individual utility functions is not observable and yields the same implications, it is not necessary to explain the phenomena observed and thus may be rejected by the rule of Occam's razor.

The observation that, following a disaster, some business firms sell some goods and services at prices below the market-clearing level similarly is not inconsistent with an unchanged pattern of tastes. The owners' wealth-maximization hypothesis already implies that the managers of certain firms have the incentive to allocate business resources to altruism in order to acquire goodwill or to avoid badwill (see Orace Johnson). A disaster clearly provides additional opportunity for such behavior. Moreover, if the structure of property rights provides business decision makers with the opportunity to increase their own welfare at the expense of the fisc or of owners' wealth, then a decrease in the price of charity induced by a disaster implies that more business resources will be allocated to charity than otherwise would have been the case (see the author, 1968).

II. Alliance Hypothesis

Hirshleifer concurred with much of my analysis,[8] but suggested that it failed to account for some of the behavior observed. To remedy the situation, he proposed to extend the alliance hypothesis of Mancur Olson and Richard Zeckhauser to post-disaster situations.

---

[4] More precisely, the inputs used by individuals in satisfying the goals which enter their utility functions include some goods and services consumed by others. "Others" may consist of only one or two relatives and friends, or may include larger groups distinguished by some characteristic (e.g., religion, race) relevant to the chooser. Benevolence implies that individuals make gifts, including tied gifts, and there is much evidence of this behavior. For some individuals, however, an increase in the consumption of certain commodities (e.g., alcoholic beverages, drugs) by others may be a source of disutility; some of the consequences of malevolence will be noted later on.

[5] See the author (1967) for a diagrammatic exposition of the two contrasting viewpoints. As usual, individual utility functions are hypothesized to be single-valued, convex, and twice differentiable.

[6] The relative price of charity falls for all individuals, including victims. In the case of some victims, the movement down along the demand curve (the price effect) may be more than offset by the decrease in the demand curve occasioned by the disaster-caused loss of wealth, yielding a reduction in the amount of charity undertaken. Charity is taken throughout to be a normal or superior good.

[7] The utility interdependence hypothesis implies that aid will decrease and eventually cease as victims recover. Following a disaster, the victims—aided by gifts and by the resumption of community activities—begin to recover and to revise the profile of their assets and liabilities to cope with the new situation. As the welfare of the victims increases, donors receive less utility from additional gifts, and aid to victims decreases and eventually stops.

[8] Thus, Hirshleifer noted that "If [community feeling] means that disaster brings about a shift in the utility function, the phenomenon lies in the realm of psychology—so there is little for the economist to discuss" (p. 4).

Briefly, the alliance hypothesis asserts that the continuation of organized society is a collective good which benefits most of society's members (see Hirshleifer, p. 6). This provides even narrowly selfish individuals with the incentive to engage in alliance-supportive activities. The duties assumed under the social contract are enforced by custom and policemen (pp. 5–7). Disasters enhance the marginal effectiveness of individual actions for survival of the alliance, and thereby give rise to good behavior. The greater the likelihood that the society will be overpowered by the disaster, however, the greater the probability that bad behavior will occur, as each individual increasingly looks out for his own narrow interests. If stress exceeds whatever point may be optimal for a society in view of its customs, culture, and size, then the alliance will collapse (pp. 8–9).

In preparing his case for the alliance hypothesis, Hirshleifer agrees that the disaster-induced increase in the relative marginal utility to an individual of victims' consumption explains " . . . why relatively better-off individuals in disasters tend to help their less fortunate neighbors" (p. 4) and " . . . the universally observed fact that relief . . . tends to flow into a damaged area from the untouched outside" (pp. 4–5). On the other hand, he finds that:

> The opposite side of the coin, the implication that those relatively worse-off tend to be less altruistic than before, is also plausible, but there seems to be no evidence relating degree of altruistic activities inversely to the degree of relative deprivation. Also, this view provides no explanation as to why *general* impoverishment is met with general "good behavior," nor as to why exceptional cases occur in which "bad behavior" is observed. [p. 5]

The behavior at issue, however, does not appear to be inconsistent with the utility interdependence hypothesis. First, lack of evidence about an implication does not provide sufficient ground for doubting its validity. If the hypothesis suggested by Hirshleifer has been deduced correctly from the axioms of consumer theory under the appropriate antecedent conditions, then it receives indirect support from the evidence pertaining to other aspects of consumer choice and it may be taken to hold until more direct evidence becomes available.[9]

More importantly, Hirshleifer is quite right in calling attention to the possibility of bad behavior following a disaster. Such behavior, however, is explicable within the existing analytical framework. *Ceteris paribus*, the decrease in the price of charity faced by an individual within the disaster area is offset—to the extent that he is also a victim—by his loss of wealth. As a result, the degree of altruism observed within a community will depend upon the extent and dispersion of the damage among its members.[10] If the disaster is localized and the individual's survival is not at stake (conditions which were implicit in previous discussions), then cooperative behavior may be expected to dominate. More tragic conditions, however, generate both lower prices of charity and greater losses of wealth. Beyond some point, the wealth effect will begin to dominate, yielding a lower level of cooperative behavior. As the seriousness of the disaster increases, therefore, not only are more individuals harmed more seriously, but the decrease in altruism implies that a victim's expectation of *receiving* aid is also reduced. *Ceteris paribus*, this will increase the relative benefits

---

[9] A rigorous test of the hypothesis in question would be helpful. In doing so, however, it would be necessary to take into account such things as changes in the enforcement of laws and differences in the relative price of charity confronting different individuals.

[10] There is also the problem of weighing acts of altruism under alternative conditions, such as a helping hand when survival is at stake relative to a gift of shelter under less trying circumstances.

(for example, survival) to be obtained from bad behavior, and more of the latter will occur. A weakening of the enforcement mechanism similarly will encourage bad behavior.[11] Altogether, it is certainly plausible that the magnitude and form of some disasters will be such that bad behavior will dominate. In general, the mix of good and bad behavior and which one will dominate will depend upon such things as the relative taste for these activities (as influenced by custom and culture), the change in their relative prices, the extent of the disaster, and the size and kinship of the group.

In justifying the case for alliance, Hirshleifer denies " . . . the premise that substantially everyone's utility map has a positive partial derivative with respect to 'other fellows' income" (p. 5). If the statement is intended to deny that substantially everyone's income enters substantially everyone else's utility function, then Hirshleifer is quite right. Such a premise, however, is not necessary to the analysis. A sufficient condition is that substantially everyone's utility function has a positive partial derivative with respect to at least *some* other individuals' income, say just a few friends and relatives. This premise seems plausible, but even weaker ones would work. The validity of economic propositions does not require that all or even substantially all actors respond to a change in circumstances. In the case of disasters, where friends and relatives living in the same community are affected, even a fairly selective response at the margin would be enough to yield the consequences predicted. And some individuals undoubtedly recognize a larger kinship group.

Having explicitly adopted a weaker premise of utility interdependence, Hirshleifer suggests that many cases of negative taste for altruism—at least at the margin—may be expected to give rise to conflict and to cloud the effect of general impoverishment upon behavior. The importance of this point, however, could easily be overstated since the disaster-induced consequences of positive and negative altruism are not wholly symmetric. Using Hirshleifer's example (p. 5), let A view keeping up with the Joneses as a problem and their income as a bad. If the Joneses become victims of a disaster and A is untouched, A will gloat and move to a higher level of utility. As long as laws are enforced, however, A will find it costly, just as he did before the disaster, to visit additional misfortunes upon the Joneses. In general, A will simply abstain from aiding the Joneses while assisting the Smiths, who may be poorer, friendlier, or whatever. Indeed, if the Joneses are hurt enough, A may even help them. None of these statements, of course, is intended to deny the possibility of bad behavior (including the settling of old scores) noted earlier.

Although the alliance hypothesis does not appear to be necessary to explain the behavior observed, its case is appealing. Individuals do form organized societies in order to reap the benefits of increased social interaction (including greater specialization), and this implies that they have the incentive to preserve the society. Nevertheless, even if disasters and other threats multiply manifold the marginal effectiveness of individual actions in preserving society (see Hirshleifer, p. 7), an individual would undertake such actions voluntarily only to the extent that *his* benefits exceeded *his* costs. Otherwise, he would take a free ride. And since the social contract at best is vague, the enforcement of alleged duties is difficult and thus presents individuals with considerable scope for free riding.[12] Custom may help, and

---

[11] Major disasters often are accompanied by the introduction of martial law, a step designed to discourage bad behavior by imposing higher penalties earlier in time.

[12] Recall that the problem is to explain *voluntary* cooperation. Although policemen seek to enforce society's

Hirshleifer notes that the social contract is partially self-enforcing as education is used to convert duties into customary behavior (p. 6). However, on this tack, alliance seems to explain why the welfare of others is a good. The view that some utility interdependence is a desirable survival characteristic is encouraged by the observation of altruistic behavior among primates and other animals (see Dennis Krebs, pp. 261–62 and Konrad Lorenz), and would help to explain why, on the postdisaster evidence available, alliance behavior seems to be indistinguishable from utility interdependence.[13] Hirshleifer does not suggest tests which could be used to discriminate rigorously between the two alternatives, and such tests—for the reasons noted earlier—seem difficult to formulate.[14]

III. Informal Insurance

Douty sought to establish that postdisaster cooperative behavior may be wholly explained by a narrowly conceived view of self-interest, one which excludes utility interdependence entirely (p. 583).[15] Basing his case upon an expanded version of Hirshleifer's alliance hypothesis, he proposed informal insurance as the key explanatory hypothesis.

According to Douty, consensual agreement[16] provides the institutional environment which specifies the range of actions an individual can undertake in his own behalf and permits market interdependence and specialization (p. 584). A major task of government is to make sure that the benefits of stable institutions are widely diffused within a society (p. 584).

A disaster initially fragments a community into small kinship groups of family and close associates. As soon as the individual has been assured of the survival of members of his kinship group, however, he becomes concerned with the survival of the larger community and with the restoration of a viable institutional framework (pp. 584–85). This increase in community feeling, which results from the individual's memory of predisaster institutions and from his perception (clouded by uncertainty) of his current situation relative to the rest of the community (p. 584), suggests to Douty that the remaining stock of "necessity goods" must be distributed in such a way as to allow the victims to survive without leaving the disaster zone (p. 584). Since the prices charged must be within the means of all the victims, and since many victims are without accessible liquid funds, Douty concludes that nonprice rationing schemes must be adopted. Owners of necessity goods are pressured to conform (p. 585).

---

laws, there is no evidence that they typically seek to enforce informal rules of cooperation following a disaster. Some laws (e.g., liability) actually discourage such behavior.

[13] Hirshleifer notes other instances of alliance behavior, such as grueling hours worked by Washington bureaucrats and willingness of soldiers to die. All sorts of people work hard at their jobs, however, and alliance activity would have to be distinguished from more normal drives such as wealth and power. Patriotism, including the willingness to accept a nonzero probability of dying in war, appears to be a useful survival characteristic for groups of individuals and may be explained by alliance activity. On the other hand, it may also be explained by altruism (e.g., protect one's family), self-interest (e.g., earn the benefits of being a hero), duress (e.g., fight or be shot), play, and other motives either singly or in combination. As noted earlier, such things as custom, culture, and the size of the group play the same role under either altruism or alliance.

[14] It may be argued that altruism relates primarily to the redistribution of goods and services whereas alliance concentrates upon the desires or opportunities for continued production. This distinction, suggested to me by Hirshleifer, seems worth pursuing further.

[15] The reader should be reminded that Douty died after he had submitted his paper but before he had an opportunity to respond to referees' comments. M. W. Reder kindly edited the manuscript (see Douty, title footnote, p. 580), but it must be presumed that he hesitated to undertake major changes that might not have been acceptable to the author. Had Douty been able to revise his paper, he might well have avoided some of the criticisms raised below.

[16] Douty indicates that his use of "consensual agreement" corresponds to Hirshleifer's use of "alliance," see fn. 10, p. 585.

According to Douty, "Reconciling this type of behavior with the hypothesis of individual utility maximization . . . presents an interesting theoretical challenge with several different, though not mutually exclusive answers" (p. 586). First, families and friends are linked together by unwritten, mutual insurance contracts against economic adversity. Strangers are included in the coverage as the community, responding to pressure induced by the disaster, acts as an informal reinsurance society to backstop the primary insurance network. Secondly, political, religious, business, and other community leaders recognize that their postdisaster activities are facilitated by such things as stable relationships and a respect for law and order. Accordingly, they press for and obtain community cooperation because they have the ability to reward and to punish. Thirdly, a disaster weakens the enforcement of private property rights.[17] This provides greater scope for community supervision of individual activities, thereby constraining individual choices toward more altruistic behavior.[18] In summary, the main thrust of Douty's argument is that individuals are tied together by an informal network of mutual insurance enforced by social pressure. When a disaster occurs, victims collect.

The informal insurance hypothesis has some initial appeal. Individuals normally sign a variety of formal insurance contracts. In the absence of any evidence to the contrary, it seems reasonable to suppose that they also execute informal insurance agreements. Following a disaster, the payment of compensation would then give rise to seemingly charitable behavior. Although this possibility had already been noted in the literature as a phenomenon additive to charity (see the author, 1968, pp. 528–29), its presentation by Douty as the key explanatory hypothesis is almost convincing on a casual reading. More careful examination, however, uncovers some serious flaws.

Perhaps the most striking flaw is methodological. Several passages in Douty's presentation suggest the inference (for example, p. 587) that the informal insurance hypothesis is superior to the utility interdependence hypothesis on the purely logical ground that it yields the same implications even though it uses fewer initial hypotheses. Indeed, it is difficult to interpret the main thrust of his paper in any other way. The minimum condition necessary to justify such an application of Occam's razor, however, is that both hypotheses yield identical implications. It simply is not enough to argue, as Douty does, that both imply altruism. If some of the lower level implications differ—and, as will be shown later, some do—then the relevance of the competing hypotheses can only be determined empirically. In the absence of such evidence, and none is offered, utility interdependence cannot be ruled out. Moreover, to exclude it would require more rather than fewer initial hypotheses.

Disregarding disaster-related behavior, there is a good deal of evidence that individuals do take others' welfare into consideration. For example, a variety of institutions (for example, most of the agencies receiving support through local United Giver campaigns) annually receive millions of dollars from anonymous contributors who could have given less (say, zero) without decreasing any of their present or future claims to assistance. Similarly, a good deal of insurance (for example, life) is for the benefit of others. This and other behavior is generally attributed to utility interdependence, and the hypothesis is now presented routinely in a variety of texts in economic theory (see, for example, Armen Alchian and William Allen, pp. 166–72; Gary Becker, p. 126).

---

[17] According to Douty, "In the aftermath of a disaster, courts cannot function and soldiers cannot be mobilized" (p. 587). This statement would narrow the analysis to an unnecessarily small category of disasters. In particular, it would exclude most if not all examples of disasters used by Douty. Accordingly, it seems best to disregard it.

[18] It is not clear why this should be the case. As noted earlier, a breakdown of the enforcement mechanism seems to encourage bad behavior. At least in the United States, major disasters typically evoke the mobilization and deployment of National Guard units reportedly to maintain order and prevent looting. This suggests that otherwise bad behavior would have increased to unacceptable levels.

If individual choices normally reflect a concern for the welfare of others, then to exclude utility interdependence in postdisaster periods requires the introduction of additional statements in the theory. Such statements yield a more complex rather than a simpler theory, and their introduction must be justified on methodological and, ultimately, empirical grounds. In particular, it is necessary to show either that the general utility interdependence hypothesis is false or that it is inapplicable in postdisaster periods. Douty does not even question the general applicability of the hypothesis. Indeed, he uses it to explain transfers from donors outside the disaster area (p. 588). Nor does he attempt to show that it is inapplicable in postdisaster periods. He merely offers a substitute hypothesis. But in the absence of any theoretical justification, it is clearly inappropriate—however convenient it might be—to ascribe *any* transfers from without to utility interdependence and *all* transfers from within to insurance or even to informal contracts of all types. Indeed, since information, search, and similar costs are lower for individuals within the disaster area, the latter may be expected to be even more generous—other things being the same—than individuals outside the disaster area.

The viability of any system of contracts depends closely upon the effectiveness of the enforcement mechanism, and Douty's analysis leans entirely upon social pressure for this purpose. There is little indication, however, why a utility-maximizing individual would have the incentive either to meet his own informal obligations or to incur costs to press others to meet their alleged, informal obligations. Under a narrow view of self-interest, an individual will seek to take a free ride. In particular, he will exert pressure on others only if thereby he can increase his receipts as a victim or decrease his contributions as a payer. And in choosing the extent to which he will meet his obligations and the amount and kinds of pressure he will bring to bear on others, he will take into account only *his* gains and *his* costs.

Postdisaster circumstances are ideally suited to free (if not easy) riding. The informal contracts discussed by Douty (and by Hirshleifer) relate groups of individuals (for example, victims and nonvictims) rather than specific individuals. Thus, it would be relatively easy for an individual to claim to have suffered greater losses than he actually had, or to claim to have already contributed, or any combination of these and other strategies intended to maximize his present wealth. No one is responsible for keeping track of who gave what to whom, and no individual (for example, the insured) has the incentive to make sure that another individual (for example, the insurer) is meeting his obligations. Moreover, legal enforcement agencies are constrained by formal laws, particularly those relating to due process and to other safeguards of individual rights. Together with the general disruption of normal information channels and the occupation of enforcement agencies with other tasks (for example, fighting fires, clearing rubble, coordinating outside help), the cost of free riding would be relatively low. Accordingly, it seems reasonable to conjecture that relatively few individuals would be constrained to meet their own obligations or to press others to meet theirs.

Since nonbeneficiaries have the incentive to shirk, social pressure would lack the broad base necessary to make it effective. After all, government is social pressure writ large and endowed with a monopoly on coercion in order to make enforcement viable.[19] Leaders' exhortations are not enough.

Even within the narrow approach chosen by Douty, however, there are no obvious reasons for limiting all informal contracts to insurance, which provides for the compensation of the givers if and only if they in turn become victims. All other informal contracts, such as loans and barter, also have to be taken into account.

Informal loans certainly would account for some seemingly charitable behavior. Immediately following a disaster, lending institutions would find it costlier than usual to establish the credit standing of would-be borrowers. At the higher cost less information is acquired, and both the higher cost and the increased risk are reflected in higher interest rates. Moreover, many borrowers would be seeking relatively small loans for relatively brief periods of time while they sorted out their affairs, and thus formal transactions would be relatively expensive. Under these circumstances, there would be greater scope than normal for negotiating mutually advantageous, informal loans among private individuals.[20] Such loans need not be limited to family, friends, and neighbors, and could profitably be extended to others. Informal loans, particularly if extended in real goods, could easily be mistaken for charity—or for informal insurance.

Informal transfers of ownership also might account for some apparently charitable behavior. For example, the disruption of various market institutions and the resulting increase in transaction costs would encourage some barter in goods and property (for example, blankets for bandages).

Of course, any argument that informal contracts (singly or in combination) fully explain any given transfer of resources must show that the transactions occur at the appropriate market prices. If the prices charged are below their market levels—after taking the appropriate pecuniary and nonpecuniary variables into account except those relating to utility interdependence—then the differential represents a transfer of resources that has to be explained some other way. In such an event, utility interdependence would be a prime candidate to explain the residual.

A more catholic approach to postdisaster altruism, one which consolidates most of the characteristics already noted, might be described as the public finance view of resource redistribution. Following a disaster, informal social arrangements—including some providing for the use of force against unwilling participants—are used to tax certain members of the community and to transfer these resources to others, including victims. One advantage of this approach is that it allows for involuntary transfers.[21] The question of why the informal tax system exists and why its provisions are enforced, however, remains open. The investigator is forced back to theories of the state (see, for example, Anthony Downs), utility interdependence (see, for example, Harold Hochman and James Rodgers; but see also Gordon Tullock), insurance, and so on. Since voluntary transfers apparently account for most postdisaster altruism observed (see Dacy and Kunreuther; Douty), however, this approach will not be pursued further.

---

[19] Liberal disaster bills passed by Congress in recent years do not appear to support the insurance hypothesis. Indeed, the "liberality" of the bills in itself is evidence of the gift component. Such gifts are not inconsistent with the incentive present in democratic (and other) constitutions to use general tax funds to benefit special interest groups.

[20] The availability of low-interest loans and forgiveness grants from various government agencies such as the Small Business Administration would decrease the opportunity for informal loans, but would not eliminate it. Informal loans would still take place to tide individuals over the interim before government and other funds become available, to provide amounts too small to justify formal contracting costs, to finance activities unacceptable to government agencies, and similar options.

[21] Some involuntary transfers (for example, theft and robbery) presumably account for some seemingly charitable behavior. Thus, an individual may be induced to sell goods and services below their open market prices in order to avoid their outright theft or to avoid harm to his person and to his property. Although Douty might disagree (p. 585), it seems best not to force such transactions into the mold of informal insurance.

At this point a few comments regarding business altruism seem in order. It has been recognized for some time (see, for example, Johnson) that under certain market conditions, the traditional owners' wealth-maximization hypothesis implies some altruistic behavior as firms "give away" resources in order to acquire goodwill or avoid badwill. In discussing postdisaster behavior in my 1968 paper, I further conjectured that, under certain ownership arrangements, utility-maximizing decision makers within business firms have the opportunity to satisfy their own taste for the welfare of others by giving away *more* business resources than would otherwise have been the case.

In keeping with his desire to explain postdisaster altruism without involving utility interdependence, Douty asserts that " . . . the postulated taste for altruism is not required if the argument is reframed in terms of the degree of involvement of the firm with the stricken community and the firm's size" (p. 587). To show that altruistic behavior may be deduced from the wealth-maximization hypothesis, however, does not exclude the possibility that at least some business transfers may be charitable.

Douty's analysis, though weak in parts,[22] simply suggests once again that altruistic behavior may be deduced from the standard wealth-maximization hypothesis. In order to rule out the possibility of some charity, however, it is necessary to show either that the implications of the utility maximization hypothesis have been deduced incorrectly or that its antecedent conditions are inapplicable. Ultimately, of course, the validity of the hypothesis can only be questioned empirically. Douty does none of these things.[23]

A final point deserves note. If a firm is to acquire goodwill through altruism, there must be a presumption that charity is a good within the community: the welfare of others matters. "Free" advertising is generally negligible, and narrowly selfish individuals would increase their patronage of "charitable" firms only to the extent that they expected thereby to benefit from *future* disaster-induced transfers. But even if, following a disaster, firms charged lower prices only to their own regular customers (a necessary condition to induce any increase at all in patronage), the present value of the gains expected by prospective customers would be small enough (even if the additional cost of patronizing the donor were zero) that additional patronage would be negligible.

---

[22] For example, the argument that the size and community involvement of the firm matter is vague and largely by analogy. No definition of size is provided, and some firms which fit Douty's description (e.g., brokerage houses with branch offices) do not appear to yield the desired implications.

[23] To buttress his case for the effect of firm size on altruism, Douty notes, fn. 18, p. 587, that the Southern Pacific was the largest benefactor of San Francisco following the earthquake of 1906 and that the Safeway stores in Alaska did not increase the prices of staples (some prices were actually lowered) following the earthquake of 1964. These observations, however, are too casual to be meaningful. For example, was the Southern Pacific the "largest" firm in San Francisco? Was the Safeway's rank order as benefactor similar to its rank order for size? How did other firms behave? Were other factors actually at work? Thus, Johnson's tentative study of corporate philanthropy does not support Douty's conjecture regarding size. His results indicate that the ratio of charitable contributions to profits does not vary directly with asset size, and suggest that other variables (say, degree of competition) account for the behavior he observed.

IV. Range of Application of the Competing Hypotheses

The analysis so far suggests that alliance activities, informal contracts, and utility interdependency may all account for some postdisaster altruism. Obviously, it would be helpful to establish the range of application of these hypotheses. Although a definitive answer must wait until more rigorous empirical evidence becomes available, various theoretical and empirical considerations encourage a preliminary answer.[24]

Utility interdependence already appears to provide the major if not the sole explanation for voluntary resource transfers from individuals *outside* the disaster area. The case for informal insurance is particularly weakened by enforcement problems and by the lack of incentive to make anonymous contributions, and even Douty acknowledges that pure altruism accounts for much aid from outsiders (p. 588). Alliance activity similarly would be strained to explain all such behavior (for example, foster parent programs).

Turning to altruistic behavior *within* the disaster area, a crucial characteristic which distinguishes insurance from charity is that the individuals who participate in an insurance scheme expect to be compensated should they become victims later on. Among other things, this implies that an individual will reveal a strong preference to help those victims who offer the best evidence of being able to compensate him in the future should the occasion arise. A donor, on the other hand, will prefer to aid those who, *ceteris paribus*, seem to have suffered most from the disaster. As a result, an insurer will prefer to aid young, healthy, wealthy individuals who are temporarily distressed rather than old, ill, and poor individuals: the latter are much less likely to be around and to be able to compensate the giver if and when the occasion arises. Although even the old, the weak, and the poor eventually might be aided under some sort of an informal assigned risk plan enforced by social pressure (how?), the expectation is that they would be helped last and least. A donor, on the other hand, will reveal a stronger preference for these people—controlling for family, friendship, and similar ties—exactly because they are less able to take care of themselves. Theoretical considerations noted earlier suggest that the insurance hypothesis is not likely to prevail. This conclusion is supported by strong evidence from psychological studies indicating that the single most important characteristic of recipients is dependency (see Krebs, pp. 277–79).

Alliance activity, particularly of the kind induced by custom, appears to be indistinguishable from charity. Indeed, as noted earlier, it could be used to explain it. Altogether, utility interdependence appears to have significant explanatory power within the disaster area as well.

Other informal contracts, where the parties to the exchange belong to amorphous groups and fulfillment of the contract is essentially random, are subject to the same limitations of the informal insurance program. Transfers of a more traditional nature, where the terms of the contract are specified and the individual parties to the transaction are clearly identified but simply do not bother to sign a formal contract, would give rise to behavior which to an uninformed bystander might seem to be charitable. It should be possible, however, to identify such events and to treat them accordingly.

---

[24] Douty's position on the range of application of the informal insurance hypothesis at best is equivocal. Although the whole thrust of his argument is that it explains the behavior observed without reference to utility interdependence, he concludes the theoretical presentation of his case with the statement that "Nothing further need be said about the characteristics of anyone's utility function, though, 'true altruism' may be present in postdisaster situations" (p. 587). But true altruism, as defined by Douty, arises from utility interdependence. Accordingly, something further *is* being said about individual utility functions: they are interdependent.

Additional research, particularly at the empirical level, obviously is desirable to clarify matters further. Beyond some point, however, the explanation of altruism properly belongs to psychology and sociology. Unfortunately, the evidence here at present is also inadequate. Psychological studies have begun to identify a number of significant characteristics of givers and of recipients,[25] but researchers have not yet found a way to measure the motivational base of altruism, and the concept of altruism itself is still unclear (see Krebs, p. 297). Sociological explanations of altruism have focused upon norms of social responsibility (benefactors should help those who need help) and of reciprocity (beneficiaries should help, or not harm, those who have helped them) with mixed empirical support (see Krebs, pp. 294–97). Interestingly enough for present purposes, proponents of the reciprocity hypothesis (a norm which characterizes at least Douty's position) note only one exception to its range of application: emergency situations, where the norm of giving holds (see Krebs, pp. 294–95). Why such norms should exist—if, indeed, they do—awaits further research.[26]

V. Conclusions

Economic explanations of postdisaster cooperation initially focused upon utility interdependence and business wealth-maximization. Hirshleifer, however, suggested that these explanations failed to account for some of the behavior observed and proposed alliance activity to fill the gap. Douty sought to rule out utility interdependence entirely and to explain all postdisaster cooperation in terms of narrowly conceived utility maximizing behavior.

The papers by Douty and by Hirshleifer suggest that the consequences of various informal contracts deserve to be taken into account. Informal insurance and alliance activity, however, do not appear to have sufficient power to explain all the behavior observed. The presence of utility interdependence under normal conditions, the lack of an effective mechanism to enforce informal contracts, and evidence of disaster-connected charity (for example, anonymous gifts from outside the community) suggest that utility interdependence matters in postdisaster situations.

Different instances of postdisaster cooperation may have different causes, and it would be difficult to defend any one single explanation. Presumably, some transfers may be attributed to utility interdependence, others to informal contracts of various sorts (including loans and transfers of ownership shares), and still others, perhaps antecedent to utility interdependence, to such things as alliance activity.[27]

---

[25] Krebs' recent review of the psychological and related sociological literature on altruism reports the following main conclusions. The results of experiments in which situational variables were manipulated indicate that individuals become more altruistic after experiencing success and competence as well as guilt and shame and after observing altruistic acts by others (pp. 264–77). In particular, there is evidence that individuals who perceive themselves to be competent in emergencies give more help in postdisaster situations (pp. 264, 266). The most important characteristic of a recipient in eliciting aid is dependency (pp. 277–79); interpersonal attractiveness is the only other significant variable (pp. 279–81). Although personality traits of both givers and recipients do not seem to matter (pp. 281–86), several social and demographic variables do: sex, age, ordinal position, social class, and nationality seem to affect altruism (pp. 286–94). Regarding the social roles of recipients, it appears that individuals give to those who are similar to themselves, are prestigious, and are more likely to benefit them in the future. Moreover, the receipt of favors elicits a general disposition toward altruism described as generalized reciprocity (pp. 295–97).

[26] According to Krebs, "Little psychological research has examined the norm of giving, even though it may have been antecedent to many altruistic situations" (p. 295).

[27] The reason why any good enters any individual's utility function ultimately must be selfish. The goal(s) which the good satisfies are the individual's goals, however determined, and the individual chooses the extent to which alternative goals are to be fulfilled, subject to the constraints which limit his choices.

Nevertheless, although utility interdependence may not be sufficient to explain all postdisaster cooperation, it certainly appears to be necessary—a statement which does not appear to hold for the other alternatives considered.

Polluters' Profits and Political Response: Direct Controls Versus Taxes

By James M. Buchanan and Gordon Tullock*

Economists of divergent political persuasions agree on the superior efficacy of penalty taxes as instruments for controlling significant external diseconomies which involve the interaction of many parties. However, political leaders and bureaucratic administrators, charged with doing something about these problems, appear to favor direct controls. Our purpose in this paper is to present a positive theory of externality control that explains the observed frequency of direct regulation as opposed to penalty taxes or charges. In the public-choice theory of policy,[1] the interests of those who are subjected to the control instruments must be taken into account as well as the interests of those affected by the external diseconomies. As we develop this theory of policy, we shall also emphasize an elementary efficiency basis for preferring taxes and charges which heretofore has been neglected by economists.

I

Consider a competitive industry in long-run equilibrium, one that is composed of a large number of n identical producing firms. There are no productive inputs specific to this industry, which itself is sufficiently small relative to the economy to insure that the long-run supply curve is horizontal. Expansions and contractions in demand for the product invoke changes in the number of firms, each one of which returns to the same least-cost position after adjustment. Assume that, from this initial position, knowledge is discovered which indicates that the industry's product creates an undesirable environmental side effect. This external diseconomy is directly related to output, and we assume there is no technology available that will allow alternative means of producing the private good without the accompanying public bad. We further assume that the external damage function is linear with respect to industry output; the same quantity of public bad per unit of private good is generated regardless of quantity.[2] We assume that this damage can be measured and monitored with accuracy.

This setting has been deliberately idealized for the application of a penalty tax or surcharge. By assessing a tax (which can be computed with accuracy) per unit of output on all firms in the industry, the government can insure that profit-maximizing decisions lead to a new and lower industry output that is Pareto optimal. In the short run, firms will undergo losses. In the long run, firms will leave the industry and a new equilibrium will be reached when remaining firms are again making normal returns on investment. The price of the product to consumers will have gone up by the full amount of the penalty tax.

---

[1] Charles Goetz imposes a public-choice framework on externality control, but his analysis is limited to the determination of quantity under the penalty-tax alternative.

[2] This assumption simplifies the means of imposing a corrective tax. For some of the complexities, see Otto Davis and Andrew Whinston and Stanislaw Wellisz.

No one could dispute the efficacy of the tax in attaining the efficient solution, but we should note that in this setting, the same result would seem to be equally well insured by direct regulation. Policy makers with knowledge of individual demand functions, the production functions for firms and for the industry, and external damage functions, could readily compute and specify the Pareto-efficient quantity of industry output.[3] Since all firms are identical in the extreme model considered here, the policy makers could simply assign to each firm a determinate share in the targeted industry output. This would then require that each firm reduce its own rate of output by X percent, that indicated by the difference between its initial equilibrium output and that output which is allocated under the socially efficient industry regulation.[4]

Few of the standard arguments for the penalty tax apply in this setting. These arguments have been concentrated on the difficulties in defining an efficient industry output in addition to measuring external damages and on the difficulty in securing data about firm and industry production and cost functions. With accurately measured damage, an appropriate tax will insure an efficient solution without requiring that this solution itself be independently computed. Or, under a target or standards approach, a total quantity may be computed, and a tax may be chosen as the device to achieve this in the absence of knowledge about the production functions of firms.[5]

In the full information model, none of these arguments is applicable. There is, however, an important economic basis for favoring the penalty tax over the direct control instrument, one that has been neglected by economists. The penalty tax remains the preferred instrument on strict efficiency grounds, but, perhaps more significantly, it will also facilitate the enforcement of results once they are computed.[6] Under the appropriately chosen penalty tax, firms attain equilibrium only at the efficient quantity of industry output. Each firm that remains in the industry after the imposition of the tax attains long-run adjustment at the lowest point on its average cost curve only after a sufficient number of firms have left the industry. At this equilibrium, there is no incentive for any firm to modify its rate of output in the short run by varying the rate of use of plant or to vary output in the long run by changing firm size. There is no incentive for resources to enter or to exit from the industry. So long as the tax is collected, there is relatively little policing required.

This orthodox price theory paradigm enables the differences between the penalty-tax instrument and direct regulation to be seen clearly. Suppose that, instead of levying the ideal penalty tax, the fully informed policy makers choose to direct all firms in the initial competitive equilibrium to reduce output to the assigned levels required to attain the targeted efficiency goal for the industry. No tax is levied. Consider Figure 1, which depicts the situation for the individual firm. The initial competitive equilibrium is attained when each firm produces an output, q_i. Under regulation it is directed to produce only q_0, but no tax is levied. At output q_0, with an unchanged number of firms, price is above

---

[3] See Allen Kneese and Blair Bower, p. 135.

[4] No problems are created by dropping the assumption that firms are identical so long as we retain the assumption that production functions are known to the regulator.

[5] This is the approach taken by William Baumol, who proposes that a target level of output be selected and a tax used to insure the attainment of this target in an efficient manner.

[6] See George Hay. His discussion of the comparison of import quotas and tariffs on oil raises several issues that are closely related to those treated in this paper.

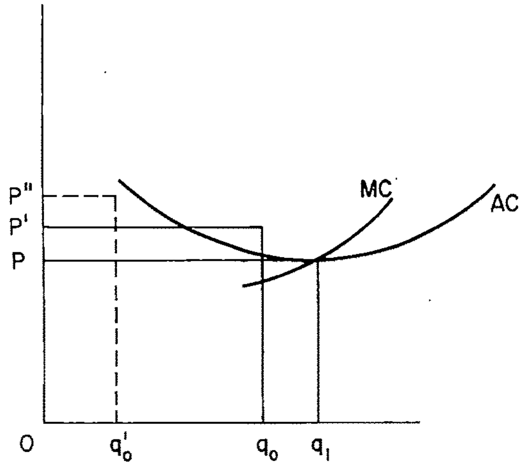

FIGURE 1

marginal cost (for example price is at P'). Therefore, the firm is not in short-run equilibrium, and would if it could expand output within the confines of its existing plant. More importantly, although each firm will be producing the output quota assigned to it at a somewhat higher cost than required for efficiency reasons, there may still be an incentive for resources to enter the industry. The administrator faces a policing task that is dimensionally different from that under the tax. He must insure that individual firms do not violate the quotas assigned, and he must somehow prevent new entrants. To the extent that the administrator fails in either of these tasks, the results aimed for will not be obtained. Output quotas will be exceeded, and the targeted level of industry production overreached.

If the administrator assigns enforceable quotas to existing firms and successfully prevents entrants, the targeted industry results may be attained, but there may remain efficiency loss since the industry output will be produced at higher average cost than necessary if firms face U-shaped long-run average cost curves. Ideally, regulation may have to be accompanied by the assignment of full production quotas to a selected number of the initial firms in the industry. This policy will keep these favored firms in marginal adjustment with no incentives for in-firm adjustments that might defeat the purpose of the regulation. But even more than under general quota assignment there will be strong incentives for firms to enter the industry and to secure at least some share of the rents that the restriction of industry output generates. If the response to this pressure should be that of reassigning quota shares within the unchanging and targeted industry output so as to allow all potential entrants some share, while keeping all firms, actual and potential, on an equal quota basis, the final result may be equivalent to the familiar cartel equilibrium. No firm will be earning more than normal returns, but the industry will be characterized by too many firms, each of which produces its assigned output inefficiently.

II

When we examine the behavioral adjustments to the policy instruments in the manner sketched out above, a theory of policy emerges. Regulation is less desirable on efficiency grounds even in the presence of full information, but this instrument will be preferred by those whose behavior is to be subjected to either one or the other of the two policy instruments. Consider the position of the single firm in the fully competitive industry, depicted in Figure 1. Under the imposition of the tax, short-run losses are necessarily incurred, and the firm reattains normal returns only after a sufficient number of its competitors have shifted resources to other industries. The tax reduces the present value of the firm's potential earnings stream, whether the particular firm remains in the industry after adjustment or withdraws its investment and shifts to alternative employment. In terms of their own private interests, owners of firms in the industry along with employees will oppose the tax. By contrast, under regulation firms may well secure pecuniary gains from the imposition of direct controls that reduce total industry output. To the extent that the restriction is achieved by the assignment of production quotas to existing firms, net profits may be present even for the short term and are more likely to arise after adjustments in plant. In effect, regulation in this sense is the directional equivalent of cartel formation provided that the individual firm's assigned quota falls within the limited range over which average cost falls below price. Such a range must, of course, exist, but regulatory constraints may possibly be severe enough to shift firms into positions where short-term, and even possibly long-term, losses are present, despite increased output price. Such a result is depicted by a restriction to q_0' in Figure 1, with price at P''.

Despite the motivation which each firm has to violate assigned quotas under regulation, it remains in the interest of firms to seek regulatory policy that will enforce the quotas. If existing firms foresee the difficulty of restricting entry, and if they predict that governmental policy makers will be required to accommodate all entrants, the incentive to support restriction by regulation remains even if its force is somewhat lower. In final cartel equilibrium, all the firms will be making no more than normal returns. But during the adjustment to this equilibrium, above-normal returns may well be available to all firms that hold production quotas. Even if severe restriction forces short-term losses on firms, these losses will be less than those under the tax. Rents over this period may well be positive, and even if negative, they will be less negative than those suffered under the tax alternative. Therefore, producing firms will always oppose any imposition of a penalty tax. However, they may well favor direct regulation restricting industry output, even if no consideration at all is given to the imposition of a tax. And, when faced with an either/or choice, they will always prefer regulation to the tax.

III

There is a difference between the two idealized solutions that has not yet been discussed, and when this is recognized, the basis of a positive hypothesis about policy choice may appear to vanish. Allocationally, direct regulation can produce results equivalent to the penalty tax, providing that we neglect enforcement cost differentials. *Distributionally*, however, the results differ. The imposition of tax means that government collects revenues (save in the case where tax rates are prohibitive) and these must be spent. Those who anticipate benefits from the utilization of tax revenues, whether from the provision of publicly supplied goods or from the reduction in other tax levies, should prefer the tax alternative and they should make this preference known in the political process. To the extent that the beneficiaries include all or substantially all members of the community, the penalty tax should carry the day. Politicians, in responding to citizenry pressures, should heed the larger number of beneficiaries and not the disgruntled members of one particular industry. This political choice setting is, however, the familiar one in which a small, concentrated, identifiable, and intensely interested pressure group may exert more influence on political choice making than the much larger majority of persons, each of whom might expect to secure benefits in the second order of smalls.

There is an additional reason for predicting this result with respect to an innovatory policy of externality control. The penalty tax amounts to a legislated change in property rights, and as such it will be viewed as confiscatory by owners and employees in the affected industry. Legislative bodies, even if they operate formally on majoritarian principles, may be reluctant to impose what seems to be punitive taxation. When, therefore, the regulation alternative to the penalty tax is known to exist, and when representatives of the affected industry are observed strongly to prefer this alternative, the temptation placed on the legislator to choose the direct control policy may be overwhelming, even if he is an economic theorist and a good one. Widely accepted ethical norms may support this stance; imposed destruction of property values may suggest the justice of compensation.[7]

If policy alternatives should be conceived in a genuine Wicksellian framework, the political economist might still expect that the superior penalty tax should command support. If the economist ties his recommendation for the penalty tax to an accompanying return of tax revenues to those in the industry who suffer potential capital losses, he might be more successful than he has been in proposing unilateral or one-sided application of policy norms. If revenues are used to subsidize those in the industry subjected to capital losses from the tax, and if these subsidies are unrelated to rates of output, a two-sided tax subsidy arrangement can remove the industry source of opposition while still insuring efficient results. In this respect, however, economists themselves have failed to pass muster. Relatively few modern economists who have engaged in policy advocacy have been willing to accept the Wicksellian methodological framework which does, of course, require that some putative legitimacy be assigned to rights existent in the status quo.[8]

IV

To this point we have developed a theory of policy for product-generated external diseconomies, the setting which potentially counterposes the interest of members of a single producing industry against substantially all persons in the community. External diseconomies may, however, arise in consumption rather than in production, and these may be general. For purposes of analysis, we may assume that all persons find themselves in a situation of reciprocal external diseconomies. Traffic congestion may be a familiar case in point.

The question is one of determining whether or not persons in this sort of interaction, acting through the political processes of the community, will impose on *themselves* either a penalty tax or direct regulation. We retain the full information assumption introduced in the production externality model. For simplicity here, consider a two-person model in which each person consumes the same quantity of good or carries out the same quantity of activity in the precontrol equilibrium, but in which demand elasticities differ. Figure 2 depicts the initial equilibrium at E with each person consuming quantity Q. The

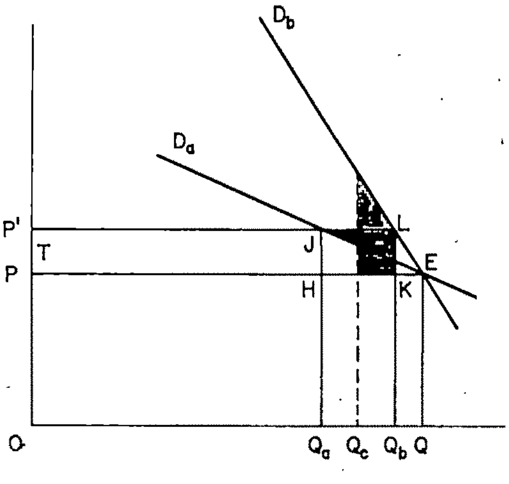

FIGURE 2

---

[7] For a comprehensive discussion of just compensation, see Frank Michelman.

[8] For a specific discussion of the Wicksellian approach, see Buchanan (1959).

existence of the reciprocal external diseconomy is discovered. The community may impose an accurately measured penalty tax in the amount T, in which case A will reduce consumption to Q_a and B will reduce consumption to Q_b. Total consumption is reduced from $2Q$ to (Q_a+Q_b), but both A and B remain in equilibrium. At the new price P', which includes tax, neither person desires to consume more or less than the indicated quantities. The government collects tax revenues in the amount $[2(PP'JH)+HJLK]$. Alternatively, the community may simply assign a restricted quantity quota to each person. If the government possesses full information about demand functions it can reduce A's quota to Q_a, and B's quota to Q_b, securing results that are allocatively identical to those secured by the tax. However, under the quota, both A and B will find themselves out of equilibrium; both will, if allowed quantity adjustment, prefer to expand their rate of consumption.

It will be useful to examine the ideal tax against the quota scheme outlined above, which we may call the idealized quota scheme. If individuals expect no returns at all from tax revenues in the form of cash subsidies, public goods benefits, or reductions in other taxes, both A and B will clearly prefer the direct regulation. The loss in consumers' surplus under this alternative is small relative to that which would be lost under the penalty tax. Each person willingly trades off marginal quantity adjustment for the more favorable inframarginal terms offered under direct regulation, given our assumptions that both instruments achieve the same overall externality control objective.

Under extreme fiscal illusion, individuals may ignore benefits from tax revenues, but consistent methodological precept requires that we allow persons to recognize the benefit side of the fiscal account, at least to some degree. Let us allow all revenues under the penalty tax to be returned in equal shares to all taxpayers. Under this arrangement, each person expects to get back one-half of the amount measured as indicated above for Figure 2. Simplifying, each expects to get back the amount $PP'JH$, which he personally pays in, plus one-half of the amount measured by the rectangle $JHKL$, all of which is paid in by B. From an examination of Figure 2, it is clear that individual A will favor the penalty tax under these assumptions. The situation for individual B is different; he will prefer direct regulation. He will secure a differential gain measured by the horizontally shaded area in Figure 2, which is equal to the differential loss that individual A will suffer under this alternative. The policy result, insofar as it is influenced by the two parties, is a standoff under this idealized tax and idealized quota system comparison.

For constitutional and other reasons, control institutions operating within a democratic order could scarcely embody disproportionate quota assignments. A more plausible regulation alternative would assign quotas proportionate to initial rates of consumption, designed to reduce overall consumption to the level indicated by target criteria. The comparison of this alternative with the ideal tax arrangement is facilitated by the construction of Figure 2 where the initial rates of consumption are equal. In this new scheme, each person is assigned a quota Q_c, which he is allowed to purchase at the initial price P. We want to compare this arrangement with the ideal tax, again under the assumption that revenues are fully returned in equal per head subsidies. As in the first scheme, both persons are in disequilibrium at quantity Q_c and price P. The difference between this model and the idealized quota scheme lies in the fact that at Q_c, the marginal evaluations differ as between the two persons. There are unexploited gains from trade, even under the determined overall quantity restriction.

It will be mutually advantageous for the two persons to exchange quotas and money, but, at this point, we assume that such exchanges do not take place, either because they are prohibited or because transactions costs are too high. Individual *A* will continue to favor the tax alternative but his differential gains will be smaller than under the idealized quota scheme. In the model now considered, *A*'s differential gains under the ideal tax are measured by the blacked-in triangle in Figure 2. Individual *B* may or may not favor the quota, as in the earlier model. His choice as between the two alternatives, the ideal tax on the one hand and the restriction to Q_c at price *P* on the other, will depend on the comparative sizes of the two areas shown as horizontally and vertically shaded in Figure 2. As drawn, he will tend to favor the quota scheme, but it is clearly possible that the triangular area could exceed the rectangular one if *B*'s demand curve is sufficiently steep in slope. In any case, the choice alternatives for both persons are less different in the net than those represented by the ideal tax and the idealized quota.

While holding all of the remaining assumptions of the model, we now drop the assumption that no exchange of quotas takes place between *A* and *B*. To facilitate the geometrical illustration, Figure 3 essentially blows up the relevant part of Figure 2. With each party initially assigned a consumption quota of Q_c, individual *A* will be willing to sell units to individual *B* for any price above his marginal evaluation. Hence, the lowest possible supply price schedule that individual *B* confronts is that shown by the line *RL* in Figure 3. The maximum price that individual *B* is willing to pay for additional units of quota is his marginal evaluation, shown by *SL*. The gains-from-trade are measured by the triangular area *RLS*. The distribution of

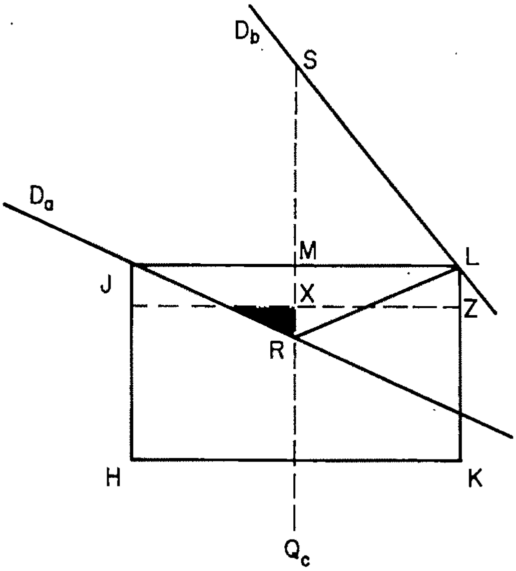

FIGURE 3

these gains will, of course, be settled in the strict two-man setting by relative bargaining skills, but let us assume that individual *B*, the buyer, wants to purchase consumption quota units from *A*, but also to do so in such a way that individual *A* will come to prefer this system over the tax. To accomplish this, he must insure that *A* gets a share of the net gains at least equal to the area *RML* on Figure 3. Individual *B*, the buyer, retains gains of *MSL* under this division of the spoils. But in this arrangement, both persons are indifferent as between the policy alternatives. The system is on the Pareto frontier, and the quota scheme plus the exchange process produces allocative and distributive results identical to those generated under the ideal tax. This becomes the analogue of the Coase theorem in the context that we are examining.[9]

V

These somewhat inconclusive results may seem to provide anything but a positive theory of policy akin to that presented with respect to production externalities. The comparisons are, however, a necessary stage in developing such a theory. Recall that we have made these comparisons under the most favorable possible assumption concerning anticipated return of revenues under the penalty tax. In the real world, individuals will not anticipate that these will be returned dollar-for-dollar, and they will tend to place at least some discount on the value of benefits that they expect.

---

[9] See Ronald Coase. For a related extension of the Coase theorem, see Buchanan (1973).

Let us say that each person expects an aggregate benefit value of only 80 cents on the dollar from tax revenues collected under the penalty tax. Consider what this single change does to the results of the last comparison made, that which involves proportionate quota assignments along with a free market in quotas. In this case, individual B, the buyer, can offer individual A, the seller, more than the amount required to make him prefer the quota alternative, while himself continuing to secure differential benefit under this alternative. Individual A's differential gains from the ideal penalty tax are reduced to the shaded area in Figure 3. By paying individual A the amount measured by RML, he has improved A's position relative to the penalty tax. And, in the process, he has retained for himself a differential gain measured by the area $MXZL$. Both persons in full knowledge of the alternatives will prefer the quota system, and political leaders will presumably respond by opting for regulation.

The same reasoning can readily be extended to apply to any quota system. In the idealized quota assignment first considered, we demonstrated that one person would favor the penalty tax and the other the quota. Individual A, who favors the penalty tax, loses no consumer's surplus, and he does expect to secure an income transfer through the return of tax revenues. When we modify the assumptions concerning expectations of the value of returned revenues or benefits, however, this conclusion need not hold. Individual A will, of course, expect to get back in benefits some part of the tax revenues paid in by B that is in excess of that contributed by A himself. If, however, individual A applies the same discount factor to all revenues collected, the deadweight loss may more than offset the income transfer effect. Examination of Figure 2 indicates that under the 80 percent assumption, one-fifth of the area measured by $PP'JH$ will represent deadweight loss to A from the revenues that he pays in. This deadweight loss may well be larger than the measure of the income transfer that he expects, which amounts to 80 percent of the horizontally shaded area in Figure 2. Once we introduce any plausible discount factor into the expectation of individuals concerning the return of tax revenues, it is relatively easy to demonstrate situations under which both persons may be led by private self-interest to favor the direct regulation alternative.

VI

We have developed a positive theory of externality control policy for both the production and consumption interactions under highly abstract and simplified models which allow us to isolate influences on policy formation which have been neglected. Decisions on the alternative policy instruments in democratic governments are surely influenced by the preferences of those who are subjected to them. The public-choice approach, which concentrates attention on the individual's choice as between policy instruments, allows us to construct hypotheses that explain the prevalence of direct regulation.[10] For economists who continue to support the penalty tax alternative, the analysis suggests that they had best become good Wicksellians and begin to search out and invent institutional arrangements that will make the penalty tax acceptable to those who are primarily affected.

---

[10] Much of the analysis developed in this paper can be applied more or less directly to policy alternatives proposed in the energy crisis of late 1973 and early 1974. For such application, see Buchanan and Nicolaus Tideman.

Durability of Consumption Goods Reconsidered

By TEDDY T. SU*

Recent progress in the durability analysis of consumer durables has been inspired by the theory of investment.[1] In 1961 Henry Miller, Jr. applied the theory of investment to a study of optimal allocation of consumption expenditures between durables and nondurables, and proposed an optimum replacement policy for consumer durables. Subsequently, David Martin discussed the effects on durability of monopolization of a perfectly competitive market. More recently, E. Kleiman and T. Ophir, David Levhari and T. N. Srinivasan, Richard Schmalensee (1970), and Peter Swan successively examined the durability of consumer durables and compared the optimum choice of durability under perfect competition and pure monopoly. Contrary to the conclusions of Levhari and Srinivasan, Swan concluded in his recent papers that a monopolist would produce goods of the same durability as competitive firms. It should be noted that Swan made his analysis using parts of the theoretical apparatus developed by Friedrich and Vera Lutz.[2] Moreover, Swan's ingenious idea of transforming a profit-maximization problem into a cost-minimization problem seems to coincide with Vernon Smith's early argument.[3] The only flaw in Swan's analysis is that the durabil-

[1] The first mathematical model on durability analysis of durable equipment is found in Wicksell's discussion of "Akerman's Problem," which was published in 1923 and translated into English in 1934. Later on, durability analysis became an important part of investment theory as seen in the works of Friedrich and Vera Lutz, and Vernon Smith. Although consumer durables and capital goods have some characteristics in common, discussion of the durability or replacement problem seems to refer solely to capital goods prior to 1960.

[2] The Lutzes discussed the nature of economic horizon and took profit maximization as a firm's objective, and so did Swan. One of the objective functions used by the Lutzes, p. 120, is

$$G = \left[\int_0^n Re^{-rt}dt - \phi(n)\right](1 + e^{-rn} + e^{-2rn} + \dots)$$
$$= \frac{R}{r} - \frac{\phi(n)}{1 - e^{-rn}}$$

Where G = goodwill or net profit, R = price of the product or service, n = lifetime of the durable, $\phi(n)$ = cost of the durable or service, and r = interest rate. "So long as the rate of interest is a constant, the condition for the optimum lifetime of each durable good in the infinite chain runs entirely in terms of costs" (Lutz and Lutz, p. 121). The condition for the optimum durability of durables in an infinite horizon provided by the Lutzes, p. 120, is

$$\phi'(n) = \frac{r}{(1 - e^{-rn})}\left[\phi(n)e^{-rn}\right]$$

Except for notation, Swan when dealing with the optimum durability of the one-hoss shay used the same objective function and arrived at the same condition. See Swan (1970), p. 886.

[3] Criticizing the profit maximization approach taken by the Lutzes, Smith (1959) argued, "By definition . . . the act of replacement should not affect any output dimension . . . replacement is concerned with minimizing the cost of producing a given output" (p. 73). Thus Smith regards optimum replacement as least cost production. Smith's model so formulated has aimed at minimizing the annual cost of the service flow in an infinite horizon. He states: "This earlier theoretical literature of replacement theory is almost wholly concerned with the replacement of machines with units of identical type. It is therefore puzzling to find such tenacious adherence to a profit maximization formulation of the model, since, in the absence of technological changes in equipment, the replacement decision cannot possibly affect either price or output" (1961, p. 131). Swan appears to be unaware of Smith's argument when he endeavors to prove that the firm's sales revenue is independent of durability choice.

ity problem has been examined merely from the supply side, i.e., the standpoint of producers. A similar flaw is found in the durability analysis of the other writers mentioned above. Although the consumer's version or demand side of durability analysis was discussed briefly by Hans Brems in 1951 and revised in his more recent book, it remains to be generalized and integrated with the supply side. The objective of this paper is to reconsider the supply side of durability analysis in conjunction with the demand side neglected by earlier writers. A similar objective seems to be embodied in papers by Schmalensee (1974) and Richard Parks which incorporate the consumer's decision in the formulation of optimum durability. Parks considers transaction and operating costs in connection with the purchase and use of one-hoss shay durables while Schmalensee introduces the optimum choice of maintenance effort in a model dealing with "radioactive decay" durables, provided that a market is composed of homogeneous consumers. Under the same essential assumptions,[4] Swan's argument, while supported by Parks, is rebutted by Schmalensee (1974), who has proposed that durability is dependent on market structure in the sense that monopoly rental policies, while yielding the same result as competitive sales and rental policies, differ from monopoly sales policies. Schmalensee's propositions are supported by the results of the present analysis centering on the consumer's choice of durability. However, this study shows that the monopolist's choice of durability could be the same under the sales policy as under the rental policy though it would distort consumers' choice.

In light of the Lutzes' analysis, consumer durables are classified into the one-hoss shay and diminishing-efficiency varieties. Since the lifetime of one-hoss shay durables is by definition a technical parameter and cannot possibly be adjusted by consumers, only diminishing-efficiency durables will be discussed in this paper.

I. The Demand Side of the Durability Problem

If firms rent rather than sell durables, the demand side of durability analysis will be irrelevant, because under the rental policy firms determine both the quality and the optimum time for replacement of durables. Hence, this section will deal only with those durables which are sold by firms to consumers. The quality of a durable is determined by the firms, but buyers of the durable may choose the optimum time of replacement.[5] Note that the lifetime of a given durable may be extended by repairs. Let us assume that consumers have purchased a durable good of quality α. The consumer's objective is to minimize the per unit expense of service rendered by the durable. The price of the durable, P, is assumed to be positive and to be a monotonically increasing function of α.[6] The variable α is an ordinal quality index. In mathematical notation,

---

[4] The present study retains the following assumptions made by Levhari and Srinivasan and adopted by Schmalensee, Swan, and Parks: (i) An economy is in the stationary state of long-run equilibrium; (ii) Returns to scale are constant; (iii) Cost functions of firms are identical; and (iv) Both consumers and producers have perfect foresight. Recently Sieper and Swan have relaxed assumption (i), and Parks has apparently removed assumption (iv) when he considers heterogeneous consumers and monopoly discrimination.

[5] It is necessary to distinguish durability or quality (α) from lifetime or replacement period (T) if the two variables α and T are determined by different decision units. In investment theory, durability and lifetime are used interchangeably, because capital equipment is manufactured and used by the same decision unit, producers. In the case of consumer durables, α and T are distinct variables because producers and consumers may make different decisions regarding durability. Such a distinction becomes trivial only if α and T are related identically under varied market conditions.

[6] To be precise, P is also a function of Q, i.e., $P=P(\alpha, Q)$, where Q is the quantities demanded and supplied. This analysis has not explicitly incorporated Q into the model, because the choice of α and T is independent of equilibrium stock, Q, corresponding to a zero excess demand.

$$(1) \qquad P = P(\alpha) > 0 \qquad \text{for any } \alpha$$

and $P'(\alpha) > 0$.[7] For a diminishing-efficiency durable, maintenance and repair are required to prevent efficiency from falling as the durable ages. Let M represent the total operating expenses on maintenance and repair over the useful life T of the durable.[8] The present value of the total maintenance and repair expenses over T periods may be expressed as

$$(2) \qquad M = \int_0^T R(\alpha, t)e^{-rt}dt \qquad \text{for } T > 0$$

where $R(\alpha, t)$ denotes the operating expenses incurred by the durable of quality α in period t, and r is the rate of interest or discount; r is assumed to be constant throughout the useful life T of the durable.[9] Properties of maintenance and repair suggest that operating expenses increase with the age of the durable and are inversely related to the quality. Thus $R_t(\alpha, t) > 0$ and $R_\alpha(\alpha, t) < 0$. It is noted that $M = 0$ if and only if any of the following cases occur: (i) The good concerned is nondurable and T may be assumed to be zero. This case should be treated separately, because the service flow of durables comes into being only when $T > 0$. (ii) The consumer has not put the durable into service. This case may be excluded from the analysis because no replacement problem would arise. (iii) The durable concerned is of the one-hoss shay variety. Such a durable has a constant life span over which no repair and maintenance are required. In the one-hoss shay case, the durability problem can be solved by setting $\alpha = T$ and $M = 0$.

To simplify the analysis, it is assumed that the durable is maintained and repaired continuously so that it remains "as good as new" during its useful life. Provided that the intensity of usage is uniform over time, the durable will render service evenly over T periods. Some unit of measurement is selected so that the durable provides exactly one unit of service per unit of time, and the per unit expense of the service is defined as p. The present value of the total expense of the service over T periods is

$$(3) \qquad V = \int_0^T pe^{-rt}dt = \frac{p}{r}(1 - e^{-rT})$$

If scrap value is assumed to be nil, the total expense of the durable is composed of the price (P) and the operating cost (M). Thus,

$$(4) \qquad V = P + M$$

The consumer must compromise between replacement cost and operating cost by determining an optimum life of the durable. In a given planning horizon, the sooner the durable is replaced, the higher is the replacement cost, although the operating cost is lower. On the other hand, the operating cost would run higher should the durable be replaced too late. Taking α as a parameter, the consumer must determine the optimum value of T in the following expression:[10]

---

[7] All the functions used in this paper are assumed to be continuous and at least twice differentiable. Prime represents the operation of derivative, e.g., $P'(\alpha) = dP(\alpha)/d\alpha$ and $P''(\alpha) = d^2P(\alpha)/d\alpha^2$, and subscript represents the operation of partial derivative, e.g., $R_T(\alpha, T) = \partial R(\alpha, T)/\partial T$, $R_{TT}(\alpha, T) = \partial^2 R(\alpha, T)/\partial T^2$, and $R_{\alpha T}(\alpha, T) = \partial^2 R(\alpha, T)/\partial\alpha\partial T$.

[8] Parks' paper also discussed operating costs. Parks, however, confined his analysis to one-hoss shay durables, assuming that the amount of the variable input per unit of service flow remains constant over time and is increasing with durability. His operating costs, as illustrated by electricity bills incurred in the operation of lightbulbs, are different from the costs presented here. In this analysis operating costs other than maintenance and repair are assumed to be independent of durability and will be abstracted.

[9] Even though r varies continuously over time, r can be approximated by some constant. The mean value theorem of integral calculus makes such an approximation possible.

[10] The consumer's objective function chosen by

$$(5)\quad p = \frac{r}{(1 - e^{-rt})} \cdot \left[P(\alpha) + \int_0^{\mathrm{T}} R(\alpha, \mathrm{t}) e^{-r\mathrm{t}} d\mathrm{t} \right]$$

By minimizing p in equation (5), the optimal value of T, assumed to be in the interior,[11] can be obtained from the following conditions:

$$(6)\qquad p = R(\alpha, \mathrm{T})$$

$$(7)\qquad R_{\mathrm{T}}(\alpha, \mathrm{T}) > 0$$

The first-order condition for minimum p is given by equation (6), which shows that the consumer will not replace the durable until the unit expense of the service is equal to the marginal operating cost.[12] Equation (7) is the second-order condition, which is assured by an inherent property of repair and maintenance that $R_{\mathrm{t}}(\alpha, \mathrm{t}) > 0$. By substituting the optimum value of T into equation (5), the minimum value of p is obtained. The optimum values of p and T are denoted by p^* and T*. If $p^* > R(\alpha, \mathrm{T})$, the durable should be repaired and kept in service. Conversely if $p^* \leq R(\alpha, \mathrm{T})$ the durable should be discarded. Suppose for the durable concerned $p^* > R(\alpha, \mathrm{T})$ in the initial period. If the operating cost increases with T, then there must exist some T* such that $p^* = R(\alpha, \mathrm{T}^*)$.

Let p^c and p^m be the unit expense of the service incurred by consumers under perfect competition and pure monopoly, respectively. Then equation (6) may be written,

$$(6\mathrm{a})\qquad p^c = R(\alpha, \mathrm{T})$$

$$(6\mathrm{b})\qquad p^m = R(\alpha, \mathrm{T})$$

under two different market conditions. If $p^c < p^m$ as usually asserted, and if the competitive firms choose the same degree of durability α as the monopolist, then T in (6a) should be smaller than T in (6b), i.e., $\mathrm{T}^c < \mathrm{T}^m$. In other words, the durable sold by the competitive firms would be dis-

---

Brems (1968, pp. 37–41) may be expressed as $p = P/\mathrm{T} + nm/\mathrm{T}$ where m = average price of repairs, $n = \mathrm{T}^a/\alpha$ = total number of repairs over the useful life of the durable, and a = elasticity of total number of repairs $= d\,log(n)/d\,log(\mathrm{T})$. Assume that $e^{-r\mathrm{T}} \approx 1 - r\mathrm{T}$. Equation (5) in the present paper becomes

$$p \approx \frac{P(\alpha)}{\mathrm{T}} + \frac{\int_0^{\mathrm{T}} R(\alpha, \mathrm{t}) e^{-r\mathrm{t}} d\mathrm{t}}{\mathrm{T}}$$

which, except for the discount factor, is equivalent to Brems' objective function. Furthermore, setting $\alpha = \mathrm{T}$ in equation (5) yields $p = rP/(1 - e^{-r\mathrm{T}}) + R(\mathrm{T})$ which bears a resemblance to Parks' equation (24). See Parks, p. 44. If the good concerned does not deteriorate and there is no scrap value at the end of its lifespan, Schmalensee's equation (5) becomes $p = rP/(1 - e^{-r\mathrm{T}}) + m$. The rate of maintenance expenditure m is implicitly assumed to be independent of t or T. The consumer's decision variable, which does not play any role in Parks' equation (24), is identified as m and T in Schmalensee's and my equations, respectively. It should be noted that Schmalensee has abstracted T from his analysis, and that his model holds for any value of T including $\mathrm{T} = \infty$.

[11] The optimum value of T should fall somewhere between 0 and ∞, because (i) $P(\alpha) > 0$ for any economic good; (ii) $P(\alpha)/(1 - e^{-r\mathrm{T}})$ decreases as T increases, and (iii) $\int_0^{\mathrm{T}} R(\alpha, \mathrm{t}) e^{-r\mathrm{t}} dt/(1 - e^{-r\mathrm{T}})$ is increasing with T. Proofs of (ii) and (iii) are given as follows:

$$d[P(\alpha)/(1 - e^{-r\mathrm{T}})]/d\mathrm{T} = -rP(\alpha)e^{-rT}/(1 - e^{-r\mathrm{T}})^2 < 0$$

and

$$\begin{aligned} &d\left[\int_0^{\mathrm{T}} R(\alpha, \mathrm{t}) e^{-r\mathrm{t}}/(1 - e^{-r\mathrm{T}})\right] \Big/ d\mathrm{t} \\ &= \left[R(\alpha, \mathrm{T}) e^{-r\mathrm{T}}(1 - e^{-r\mathrm{T}}) - re^{-r\mathrm{T}} \int_0^{\mathrm{T}} R(\alpha, \mathrm{t}) e^{-r\mathrm{t}} d\mathrm{t}\right] \\ &\quad /(1 - e^{-r\mathrm{T}})^2 \\ &= \left\{re^{-r\mathrm{T}} \int_0^{\mathrm{T}} [R(\alpha, \mathrm{T}) - R(\alpha, \mathrm{t})] e^{-r\mathrm{t}} d\mathrm{t}\right\} \\ &\quad /(1 - e^{-r\mathrm{T}})^2 > 0 \end{aligned}$$

[12] It is interesting to note that the optimum useful life of the durable derived by Brems is merely a special case of the result provided in (6). This can be shown. The first-order condition for a minimum p for Brems' objective function (see fn. 10) is

$$\frac{-P}{\mathrm{T}^2} + \frac{m(a - 1)}{\alpha} \mathrm{T}^{a-2} = 0$$

which can be arranged into

$$\frac{-1}{\mathrm{T}} \left(\frac{P}{\mathrm{T}} + \frac{m}{\alpha} \mathrm{T}^{a-1} \right) + \frac{ma}{\alpha} \mathrm{T}^{a-2} = 0$$

Substituting p for the terms in parenthesis yields $p = d(nm)/d\mathrm{T}$, because $d(nm)/d\mathrm{T} = ma\mathrm{T}^{a-1}/\alpha$.

carded by the consumers sooner than the same durable sold by the monopolist.

Furthermore, it is observed that if the consumer minimizes p and replaces the durable every T^* periods, he will minimize the total present expense of the durable in an infinite economic horizon.[13]

Finally, a hypothetical question is raised concerning the consumer's choice of durability α. If the consumer is offered an opportunity to choose the quality of the durable, what choice will he make? Based on the principle of minimizing p in (5), the consumer would choose such α as to satisfy the following condition:[14]

$$P'(\alpha) = -\int_0^T R_\alpha(\alpha, t)e^{-rt}dt \tag{8}$$

Equation (8) implies that the increased (decreased) operating cost of a poorer (better) durable should be just offset by its lower (higher) price.

II. The Supply Side of the Durability Problems

In order to compare the supply and demand sides of the durability problem, the costs of the service rendered by the durable must be disaggregated into two parts: production cost and operating cost.[15] The production cost is the cost of producing a new unit of the durable, and the operating cost is the cost of maintaining and repairing an old unit of the durable. Assume the operating cost to be the same for the durable of the same age whether it be under the sales or rental policies. In the case that firms adopt the sales policy, the operating cost will be incurred directly by consumers rather than by producers as in the case of rentals. With the assumptions of identical production structure and constant returns to scale, an identical cost function is obtained for both monopolies and competitive firms. Let C be the production cost of a unit of the durable. Assuming C to be a monotonic increasing function of α, we obtain

$$C = C(\alpha) \tag{9}$$

Under the rental policy, the firm's objective function may be written

$$\pi = \frac{p^s}{r} - \frac{C(\alpha)}{1 - e^{-rT}} - \frac{\int_0^T R(\alpha, t)e^{-rt}dt}{1 - e^{-rT}} \tag{10}$$

where p^s is the seller's price per unit of the services as distinguished from p which may be referred to as the buyer's price. Let Q be units of the durable demanded or supplied. The buyer's price, which is the price acceptable to the consumers, is the function of Q and T as shown in equation (5),[16] while the seller's price, which is the price offered by the producers, is the function of Q only. It is assumed that for any values of α and T there exists some Q such that $p=p^s$. The value of Q so determined is the amount of the durable demanded and supplied in the stationary state of long-run equilibrium. Since the choice of α and T is independent of Q, this paper has excluded Q from the analysis. Such an omission obviously has no effect on the re-

---

[13] Equation (5) may be expressed in the following form:

$$p = r\left[P(\alpha) + \int_0^T R(\alpha, t)e^{-rt}dt\right] \cdot (1 + e^{-rT} + e^{-2rT} + \dots)$$

In the above equation p is minimized if and only if the total present cost of the durable in an infinite horizon attains the minimum.

[14] For one-hoss shay durables, the first-order condition for optimum quality is obtained as follows: $P'(T)/P(T) = r/e^{rT}-1)$. If perfect competition is assumed or if demand and cost functions are homogeneous of the same order with respect to T, the above condition will be identical to Swan's. See Swan (1970), p. 886.

[15] Smith has made a similar classification by disaggregating the cost of durable equipment into the cost on capital account and the cost on current account.

[16] Although Q does not appear in equation (5) for the reason explained in fn. 6, the proposition of demand theory that p is a function of Q remains valid.

sult of durability choice as long as stationary equilibrium is maintained. The variable π is the present value of the total net profit in the infinite planning horizon. It is assumed that all the durables have the same useful life T and that production of the durable recurs every T periods. By choosing the proper values of α and T, the firm's objective is to maximize π in (10). The first-order conditions for maximization are obtained as follows:[17]

$$(11)\qquad C'(\alpha) = -\int_0^T R_\alpha(\alpha, t)e^{-rt}dt$$

$$(12)\qquad R(\alpha, T) = \frac{r[C(\alpha) + M]}{1 - e^{-rt}}$$

Equation (11) shows that when the quality of the product is raised (lowered), the increased (decreased) production cost is just offset by the decreased (increased) operating cost. It is similar to the condition for the maximization of net benefit that requires marginal cost be equal to marginal benefit. The left-hand term in equation (12) is the marginal cost of rendering a unit of service, and the right-hand term is the corresponding average cost. The average cost is tantamount to interest payment per unit of time on the total cost of durable goods invested in the infinite horizon. A firm, when adopting the rental policy and investing one unit of the durable every T periods, will incur a total cost of $[C(\alpha)+M]/(1-e^{-rT})$. Accordingly, the right-hand term in equation (12) could be interpreted as the service charge per unit of time paid by the firm to the bank or bondholders. Thus, equation (12) states the equality of marginal and average costs as implied by minimization of the total cost.

It is observed from equations (11) and (12) that the optimum values of α and T are not related to the price or demand side. Both monopolies and competitive firms by maximizing net profit when adopting a rental policy would minimize the cost of the provision of services at the same level of durability. This result is essentially the same as Swan's proposition. Swan has implied, however, that his result applies to the case of sales policies.

Although under rental policies no consumer choice may exist regarding durability, it is instructive to compare the firm's choice of α and T with the values of α and T desired by the consumers. This can be done by comparing (11) and (12) with (8) and (6). Under competition a zero net profit in long-run equilibrium implies that $C(\alpha)=P(\alpha)$, and that $C'(\alpha)=P'(\alpha)$ for any α. As a result, (11) is identical to (8), and (12) is identical to (6). Therefore, under perfect competition, the choice of α and T by the firms and by the consumers are identical. In case of a monopoly, however, it may be assumed that $P(\alpha)>C(\alpha)$ for any α. Hence, $R(\alpha, T)<p$ via (5) and (12). The implication is that the monopolist would put the given durable in service for a shorter period than the rational consumer would prefer.

Next, attention is called to the sales policy under which the consumers determine the value of T. The firm must take the consumer's decision into consideration and maximize π in the following expression:

$$(13)\qquad \pi = \frac{P(\alpha) - C(\alpha)}{1 - e^{-rT}} + \lambda[p^s - R(\alpha, T)]$$

where λ is a Lagrange multiplier. Since a perfectly foresighted firm would always sell the durable at the price given in the following identity:

$$(14)\qquad P(\alpha) \equiv \frac{p^s}{r}(1-e^{-rT}) - \int_0^T R(\alpha, t)e^{-rt}dt$$

---

[17] The first-order condition for an optimum quality of the one-hoss shay is $C'(T)/C(T)=r/e^{rT}-1$. By comparing this condition with that provided in fn. 14, we conclude that the choice of durability by competitive firms accords with the consumer's.

$$(16)\qquad 0 = \frac{C'(\alpha) + \int_0^{\mathrm{T}} R_\alpha(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}}{1 - e^{-r\mathrm{T}}} + \lambda R_\alpha(\alpha, \mathrm{T})$$

$$(17)\qquad 0 = \frac{R(\alpha, \mathrm{T})(1 - e^{-r\mathrm{T}})e^{-r\mathrm{T}} - \left[C(\alpha) + \int_0^{\mathrm{T}} R(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}\right] re^{-r\mathrm{T}}}{(1 - e^{-r\mathrm{T}})^2} + \lambda R_{\mathrm{T}}(\alpha, \mathrm{T})$$

$$(18)\qquad p = R(\alpha, \mathrm{T})$$

equation (13) becomes

$$(15)\qquad \pi = \frac{p^s}{r} - \frac{C(\alpha) + \int_0^{\mathrm{T}} R(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}}{1 - e^{-r\mathrm{T}}} + \lambda[p^s - R(\alpha, \mathrm{T})]$$

Substituting $P(\alpha)$ in equation (5) by equation (14) yields $p = p^s$. Its explicit form is $p(Q, \mathrm{T}) = p^s(Q)$. Thus, Q can be solved as soon as the optimum value of T is determined. The first-order conditions for maximum π in (15) are given by equations (16)–(18). Through equation (18) the firm has taken into account explicitly the consumer's decision regarding the optimum value of T. If equations (16), (17), and (18) are consistent and independent, the three unknowns α, T, and λ can be solved.

Let us examine first the solution for the competitive case. By the nature of perfect competition, the rules of free entry and survival of the fittest would drive a firm's average revenue precisely to the level of average cost in long-run equilibrium. That is, $P(\alpha) = C(\alpha)$ for any α. Hence, equation (17) can be arranged as

$$(19)\qquad \frac{[R(\alpha, \mathrm{T}) - p]e^{-r\mathrm{T}}}{1 - e^{-r\mathrm{T}}} + \lambda R_{\mathrm{T}}(\alpha, \mathrm{T}) = 0$$

Since the first term on the left-hand side of equation (19) is zero by virtue of equation (18), and $R_{\mathrm{t}}(\alpha, \mathrm{t}) > 0$ for any $\mathrm{t} > 0$, it follows immediately that $\lambda = 0$. The implications are two-fold: 1) Under perfect competition each individual firm finds it impossible to improve its profit by changing the price of the durable or service. In a stationary equilibrium, a competitive firm can make only a zero profit, whether or not there is any consumer's constraint. 2) In a competitive market, producers and consumers make the same choice regarding durability, and thereby the same optimum values of α and T result from the sales and rental policies. Under the sales policy the optimum values of α and T are determined by equations (16) and (18)[18] while under the rental policy they are determined by equations (11) and (12). By making a comparison, equations (11) and (16) are both equivalent to equation (8), and equations (12) and (18) are both equivalent to equation (6). Recall that equations (6) and (8) provide the consumer's choice of α and T.

Under perfect competition, equations (17) and (18) are identical because $\lambda = 0$. This is not the case with a monopoly. Making use of equations (5) and (18), equation (17) can be expressed as

$$(20)\qquad \lambda = \frac{-[P(\alpha) - C(\alpha)]re^{-r\mathrm{T}}}{R_{\mathrm{T}}(\alpha, \mathrm{T})(1 - e^{-r\mathrm{T}})^2}$$

where λ cannot be zero because $P(\alpha) > C(\alpha)$ under monopoly. Substituting (20) in (16) yields:

---

[18] The Lagrange multiplier $\lambda = 0$ does not imply that the constraint is ineffective. See Zangwill, p. 42.

$$(21)\quad C'(\alpha) - \frac{rR_\alpha(\alpha, \mathrm{T})[P(\alpha) - C(\alpha)]}{R_\mathrm{T}(\alpha, \mathrm{T})(e^{r\mathrm{T}} - 1)} = -\int_0^\mathrm{T} R_\alpha(\alpha, \mathrm{t})e^{-r\mathrm{t}}dt$$

As a result of durability variation, consumers would adjust their choice of T, which in turn would bring about a change in net profit. Such a change in net profit is measured by the second term on the left-hand side of equation (21).[19] This is a major factor in the difference between the rental and sales policies. Under the rental policy, consumers cannot adjust the useful life of the durable according to the cost minimization principle which equates average expense with marginal expense. No difference is made under perfect competition, however, because the equality of average expense and marginal expense is assured by the fact that the price of the durable is always set equal to the minimum cost.

When equations (11) and (12) are compared with equations (21) and (18), it is obvious that the optimum solution for α and T under the rental policy may differ from that under the sales policy managed by the monopolist. Note that the right-hand side of equation (12) can be shown to be equal to p^c, and that under monopoly p in equation (18) should be taken as p^m.

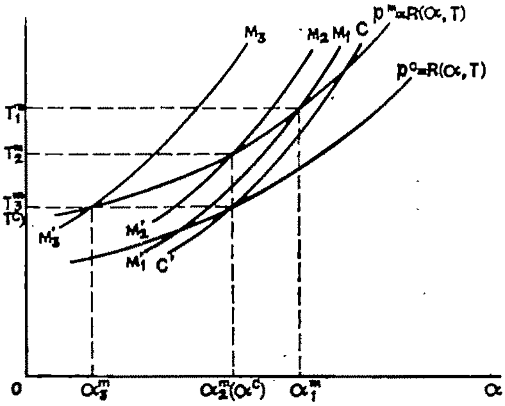

FIGURE 1

In Figure 1 equations (11) and (12) are plotted along with equations (18) and (21). The curve CC' on the $\alpha-\mathrm{T}$ plane represents equation (11), and any of the three curves M_1M_1', M_2M_2', and M_3M_3' may represent equation (21). It can be shown that the slope of CC', being positive, is greater than that of p^c or p^m,[20] and that all three curves M_1M_1', M_2M_2', and M_3M_3' are located to the left side of CC'.[21] The points α_1^m, α_2^m, and α_3^m represent the three possible values of durability chosen by the monopolist adopting the sales policy. As observed, $\alpha_1^m > \alpha^c$, $\alpha_2^m = \alpha^c$, and $\alpha_3^m < \alpha^c$. The point α^c is the optimum durability selected by the competitive firms under both rental and

---

[19] By virtue of $d\mathrm{T}/d\alpha = -R_\alpha(\alpha, \mathrm{T})/R_\mathrm{T}(\alpha, \mathrm{T})$ and $e^{r\mathrm{T}} \approx 1 + r\mathrm{T}$, the second term on the left-hand side of (21) may be expressed as $(d\mathrm{T}/d\alpha)(P-C)/\mathrm{T}$.

[20] Suppose that an interior maximum for π in (10) exists at some α and T. The second-order condition for the maximum is

$$\left[\frac{\partial^2\pi}{\partial\alpha^2}\right]\left[\frac{\partial^2\pi}{\partial\mathrm{T}^2}\right] > \left[\frac{\partial^2\pi}{\partial\alpha\partial\mathrm{T}}\right]^2$$

which gives

$$R_\mathrm{T}(\alpha, \mathrm{T})\left[C''(\alpha) + \int_0^\mathrm{T} R_{\alpha\alpha}(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}\right] > [R_\alpha(\alpha, \mathrm{T})]^2 e^{-r\mathrm{T}}$$

Taking the derivatives of (11) and (12) with respect to α and subtracting $d\mathrm{T}/d\alpha$ in (11) from that in (12) yields

$$\frac{[R_\alpha(\alpha,\mathrm{T})]^2 e^{-r\mathrm{T}} - R_\mathrm{T}(\alpha,\mathrm{T})\left[C''(\alpha) + \int_0^\mathrm{T} R_{\alpha\alpha}(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}\right]}{R_\alpha(\alpha, \mathrm{T})R_\mathrm{T}(\alpha, \mathrm{T})e^{-r\mathrm{T}}} > 0$$

Note that the slopes of the curves in Figure 1 are all positive because $d\mathrm{T}/d\alpha > 0$.

[21] Since $-rR_\alpha(\alpha, \mathrm{T})[P(\alpha) - C(\alpha)]/[R_\mathrm{T}(\alpha, \mathrm{T})(e^{r\mathrm{T}} - 1)]$ is positive whatever the values of α and T, it follows from equation (21) that $C'(\alpha) < -\int_0^\mathrm{T} R_\alpha(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}$. In contrast, equation (11) shows that $C'(\alpha) = -\int_0^\mathrm{T} R_\alpha(\alpha, \mathrm{t}) \cdot e^{-r\mathrm{t}}d\mathrm{t}$. Since the right-hand term of (11) increases with T as observed from

$$\partial\left[-\int_0^\mathrm{T} R_\alpha(\alpha, \mathrm{t})e^{-r\mathrm{t}}d\mathrm{t}\right] \Big/ \partial\mathrm{T} = -R_\alpha(\alpha, \mathrm{T})e^{-r\mathrm{T}} > 0$$

the curve of (21) should be located above the curve of (11).

sales policies. Furthermore, it follows from the earlier analysis that the monopolist adopting the rental policy would also choose durability α^c. However, it is found that the two situations $\alpha^m=\alpha^c$ and $T^m=T^c$ cannot coexist. When $T^m=T^c$, $\alpha^m<\alpha^c$; and when $\alpha^m=\alpha^c$, $T^m>T^c$. Swan's conclusion, represented by the limited case where $\alpha^m=\alpha^c$, implies that $T^m>T^c$.

It is suggested that the present analysis may be extended to study the choice of durability by a firm under a regulated monopoly environment.[22] What will be the optimum choice of durability if a monopolist is compelled to sell as well as rent his product? And what if a monopolist acts upon a court ruling to divest himself of a portion of his operations? It is implied in this study that a change in price or market structure brought about by regulation will have some effect on the choice of durability. However, the nature of change in durability level cannot be determined unless some explicit form of replacement and operating cost function is given.

III. Summary and Conclusion

In this paper it has been argued that the durability choice of the monopolist and the consumer cannot possibly be the same. Although such an inconsistency appears to be irrelevant to the durability analysis in those cases involving only the one-hoss shay goods or a rental-only policy, it may affect the optimum durability of the diminishing efficiency goods which are made solely for sales. The assumption of a perfect capital market would not resolve the inconsistency.[23] The major reason is that the consumer who bases his decision on the "price" or "expense" of the product would not put the durable in service for the same length of time as would the producers who base their decisions on the "cost" of the product. Moreover, it follows from the analysis that the monopolist's net profit should be lower under the sales policy than under the rental policy due to the effective constraint imposed by the consumers (i.e., $\lambda\neq 0$). Therefore, the monopolist would be inclined to rent the durable. Provided that the monopolist is forced to sell, the monopolist's choice of durability is *likely* to differ from that of competitive firms.[24] Under perfect competition, however, both consumers and producers would make the same choice and would be indifferent to the alternative policies.

---

[22] A referee has indicated that IBM agreed to a consent decree back in the 1950's to sell as well as rent its equipment and that the Bell System was forced by a FCC ruling to allow the attachment of privately owned PBX equipment to its lines. No doubt many interesting problems will arise from the analysis of such cases.

[23] The assumption of a perfect capital market is essential to the theory of optimum durability proposed by Swan. The same assumption was made by Douglas and Goldman in a deterministic model concerning monopolistic behavior. Although Swan has incorporated consumer-utility functions and durability choice in the mathematical appendix of his recent paper (1972, pp. 582–84), his argument is concerned merely with the durability of one-hoss shay "vehicles."

[24] In contrast with Schmalensee's result, this study does not preclude the case of $\alpha^m=\alpha^c$.

Earnings, Productivity, and Changes in Employment Discrimination During the 1960's

By JOAN GUSTAFSON HAWORTH, JAMES GWARTNEY, AND CHARLES HAWORTH*

Historians may refer to the 1960's as the decade in which Americans made a frontal attack on racial discrimination. A far-reaching Federal Civil Rights Act was passed. States passed additional legislation designed to promote racial equality and eliminate discrimination—particularly employment discrimination. Because of the political activism of the decade, a detailed analysis of the economic impact of these political changes is of great importance. This paper seeks to undertake such an analysis concentrating on the interactions between changing relative earnings, discriminatory employment practices, and relative productivity.

A number of writers have emphasized that the relative economic status of nonwhite males improved during the 1960's.[1] These findings are usually based on aggregated data, which indicate an improvement in the nonwhite/white earnings ratio (*NWER*). For instance, the *NW/W* median earnings ratio for males, age 25–64, increased 17.4 percent during the 1960's. While the size of this economic gain is of significance, its source and structure is also of great importance. The relative gains of nonwhites could have been achieved through two different mechanisms: the productivity of the nonwhite labor force may have increased relative to whites, and/or the intensity of employment discrimination may have declined.

Our analysis will seek to isolate the significance of changes in both the intensity of labor market discrimination and productivity according to race. Our findings contain some surprises. Approximately one-half of the gain in the *NWER* is attributable to the exiting of older nonwhite workers with low relative earnings combined with the entry of younger, better-prepared nonwhites who have high relative earnings. This can be illustrated by the fact that the relative gains of nonwhites within age cohort groups were modest—approximately 6 percent during the decade.

The largest gains were made by youthful, better-educated blacks. While earnings parity had not yet been attained, by 1970 the earning payoffs for young males continuing in school beyond the tenth grade were similar regardless of race.

Other researchers have argued that since nonwhites were systematically excluded from the "best" jobs, they had little incentive to acquire education and skills,[2] and were caught in "a cycle of poverty." With few skills and little education, they will have low earnings. However our findings would seem to suggest a basis

[2] This view has been articulated by Paul Siegel, Bennett Harrison, Ivor Berg, and Barbara Bergmann and Gerolyn Lyle.

for cautious optimism in this area. Changes during the 1960's have increased the relative incentives for young nonwhites to acquire additional education and skills making the cycle of poverty hypothesis considerably less applicable today than in 1960.

This paper is organized into nine sections. In Sections I through IV a model of income determination is developed and tested. Sections V to VII use cohort data to analyze the changes in earnings over time for comparable age groups, including the important effect of educational payoffs. Section VIII analyzes income changes by educational groups to determine which group received the largest income increase during the decade. Section IX summarizes the findings of the paper.

I. A Model of Income Determination

In this section a model of income determination is developed which provides information on the importance of seven factors that affect income in addition to race. The factors are incorporated as follows:

Race (1 if nonwhite);
Age—a set of dummy variables for males, age 14–24, 25–34, 45–54, 55–64, and 65 and over, with the 35–44 age grouping acting as the base);
Years of schooling;
Rural resident (1 if rural);
Southern resident (1 if South);
Annual hours worked;
Marital status—a set of dummy variables for married, spouse present (*SP*), and persons once married (divorced, separated, or widowed), with singles acting as the base group;
Veteran status (1 if nonveteran).

We expected that individual earnings would peak for males between 35 and 54. The young (under 35) and the old (over 65) were expected to have significantly lower earnings than the middle-aged groups. Schooling was expected to positively influence earnings. Other studies have shown that earnings are lower in the South than the North and, similarly, rural status has a negative impact on money earnings. Hours worked is expected to positively influence earnings. The impact of marital status is not quite so obvious, but one would expect males with spouse present to have higher earnings than single males because of the specialization in provision of monetary income that is often associated with male family responsibilities.[3] We also anticipated that veterans might acquire certain skills and/or be less likely than nonveterans to have physical or mental handicaps. Thus we expect nonveteran status to reduce earnings.

With this model of income determination we are able to distinguish between earnings which are a result of certain productivity characteristics[4] and earnings which are not explained by these factors. In many studies this unexplained portion of earnings is attributed to discrimination since it can not be attributed to a particular income enhancing characteristic. In this paper we recognize that the differential is a function of other excluded factors as well as discrimination. When racial differences in the excluded factors are held constant at two points in time, then changes in the adjusted relative earnings, which our model estimates, are indicative of changes in employment practices.

II. Empirical Results—Aggregate Earnings Function Approach

Initially, we tested the model with data on the total population—including both

---

[3] See Gwartney and Robert Stroup for evidence on the impact of marital status on earnings.

[4] The term "productivity characteristics" is used in a broad sense, including locational factors and family responsibilities in addition to other factors that are more typically thought to influence productivity.

Source: U.S. Census of Population, Public Use Sample 1960 and 1970.

white and nonwhite males—from the 1960 and 1970 *U.S. Census of Population*, Public Use Sample.[5] These results are presented in Table 1, columns 1 and 2.[6] In 1959 the unadjusted white minus nonwhite earnings were \$5,131–\$2,960, a differential of \$2,171. Adjusting the earnings differential for the seven "productivity factors" of the model reduced the *W/NW* estimated differential to \$1,000. The adjusted *NWER* was 80.5 percent compared to 57.7 percent for the unadjusted ratio (see Aggregated Earnings Approach, Table 2). In 1969, adjusting for the seven variables reduced the white-nonwhite differential from \$2,859 to the \$1,427 indicated in Table 1, column 2. The adjustment process increased the *NWER* from 66.0 percent to 83.0 percent in 1969. Thus, utilizing this method of adjustment, the seven factors of our model accounted for approximately one-half of the total *W-NW* earnings differential for both 1959 and 1969.

---

[5] This data base includes all males age 14 and over except persons who had either zero earnings or zero hours worked. The total number of males included in 1969 was 40,578 of whom 3886 were nonwhite. In 1959, the data base was 34,737 including 3385 nonwhites. All of the data presented in this paper will be for males only.

[6] An appendix containing the regression results for several alternative models and all of the supportive equations for the summary results presented in the paper is available from the authors upon request.

The independent variables of the model all have the expected signs, their magnitudes appear to be reasonable, and 11 of the 13 variables are significant at the 99 percent confidence level in both years. The "earnings functions" for the two years are parallel, indicating that the independent variables had a similar impact on earnings during the two time periods.

The *NWER*, adjusted for the seven factors, increased from 80.5 in 1959 to 83.0 percent in 1969, a gain of 3.1 percent. But in dollar terms, the *W/NW* adjusted differential actually widened during the 1960's. In money terms, the differential was $427 greater in 1969 than 1959. Measured in 1969 dollars, the gap increased by $169.

III. Differences in Earnings Functions According to Color

After adjusting for the seven factors of our model, the total population data suggest there was a small change of only 3.1 percent in the *NWER* during the 1960's. But these findings may be misleading because they implicitly assume that both whites and nonwhites have the same earnings function. The work of other researchers indicates this has not been the case. Failure to compensate for possible changes or differences in the earnings functions according to color during the 1960's could bias our estimates of changes in the adjusted *NWER* during the decade.

In order to isolate the importance of differences in the earnings functions according to color, we estimated the functions separately. Table 1, columns 3–6, presents the estimated earnings function of males according to color for both 1959 and 1969. There are, of course, several differences in these earnings functions. Since the mean earnings of nonwhite males is lower than white males, the coefficients are usually smaller. The estimated payoff for a year of education in 1959 was three times greater for whites than nonwhites—$296 versus $92. In 1969 it was two times greater—$546 versus $269. The age coefficients show a different lifetime earnings profile for nonwhites than for whites. A comparison of the age coefficients shows that the earnings of white males peak at a later age than nonwhites. This result probably reflects the overrepresentation of white males in white-collar occupations where earnings often continue to rise throughout one's working life. This age-earnings pattern was present for both 1959 and 1969.

The impact of marital and rural status was similar in 1969 and 1959. According to color, in absolute terms, the size of the coefficients for the marital and rural status variables were smaller for nonwhites, but relative to total earnings the coefficients were similar according to color. For both 1959 and 1969, southern residence reduced the earnings of nonwhites in dollar terms by approximately twice the reduction for white males. This regional difference is consistent with the findings of other researchers and supports the hypothesis that a higher degree of discrimination exists in the South.

IV. Changes in the Adjusted *NWER*—Separate Earnings Approach

Having estimated the earnings functions according to color, it is now possible to construct an estimate of earnings for one color group given the mean values of the other. This, in turn, permits disaggregating the earnings differences of the color groups into two components. First, one can derive a hypothetical *NWER* assuming that both white and nonwhite males had identical "earnings related" characteristics (i.e., the same mean values for years of schooling, age, veteran status, and other independent variables) but still possessed their respective "earnings functions." This might be called the

TABLE 2—ESTIMATED CHANGES IN THE *NWER* BETWEEN 1959 AND 1969[a]

	1959	1969	Change
Actual *NWER*	57.7	66.0	+14.4
Hypothetical *NWER*			
Identical Productivity: Different Earnings Function			
Both had white mean productivity values	70.8	79.0	+11.6
Both had nonwhite mean productivity values	70.9	76.9	+ 8.5
Identical Earnings Functions: Different Productivity Mean Values			
Both had white function	81.3	86.0	+ 5.8
Both had nonwhite function	81.5	83.5	+ 2.5
Aggregate Earnings Approach: Identical Earnings Function			
Different Mean Values	80.5	83.0	+ 3.1

Source: See Table 1.
[a] Shown in percent.

"identical productivity" estimate.[7] It removes the impact of differences, according to color, in the "productivity variables" of our model, but the impact of racial differences in the earnings functions will remain.

This hypothetical identical productivity *NWER*, presented in Table 2, will be less than unity solely because nonwhites on average receive a lower payoff for the productivity characteristics of our model. Assuming nonwhites (as well as whites) had the white mean value for the productivity variables, but still possessed the nonwhite earnings function, the hypothetical nonwhite earnings would have been $3634. Thus in 1959, if both groups had possessed the white mean values for the productivity variables of this model, the estimated *NWER* would have been $3634/$5131, or 70.8 percent. Assuming that both groups possessed the nonwhite productivity characteristics in 1959, the estimated hypothetical identical productivity *NWER* was 70.9 percent.

For 1969, our estimates suggest that nonwhites of identical productivity would have received between 76.9 percent (using nonwhite productivity variables for both color earnings functions) and 79.0 percent (using white mean values) of white male earnings. Thus when comparing white and nonwhite males who are similar with regard to seven productivity characteristics the *NWER* increased by between 8.5 and 11.6 percent during the 1960's.

A second hypothetical *NWER* can be developed using an "identical earnings function" assumption. This estimate uses the existing differences in the mean values of the earnings related variables of the color groups but assumes identical earnings functions according to color. For this hypothetical measure, there are no differences according to race in the *payoffs* from

---

[7] Two hypothetical estimates can be derived. The "identical productivity" estimates are:

$$\frac{Y_n(P_w)}{Y_w(P_w)} \quad \text{and} \quad \frac{Y_n(P_n)}{Y_w(P_n)}$$

where Y represents the actual earnings function according to color and P the actual mean values for each earnings related characteristic (the independent variables). Whites and nonwhites are denoted by w and n, respectively. The numerator of the first estimate is the hypothetical earnings of nonwhites assuming they had their actual earnings function but the white productivity characteristics. This is divided by the actual earnings of whites yielding the first identical productivity estimate. For the second estimate, the denominator is the hypothetical earnings of whites assuming their actual earnings function but the nonwhite mean values for each of the productivity characteristics. The actual nonwhite earnings is divided by this estimate to derive a second identical productivity estimate.

possession of productivity characteristics, but the presence of existing productivity differences remain.

The identical earnings function estimates also appear in Table 2.[8] For example, in 1959 if nonwhite males had received the white earnings function payoffs they would have earned $4173, while whites actually received $5131 for a hypothetical *NWER* of 81.3 percent. Using the black earnings functions, the hypothetical *NWER* was almost identical—81.5 percent. In 1969, the comparable estimates were 83.5 and 86.0 percent, indicating a gain of between 2.5 and 5.6 percent. This suggests that there was an improvement in the distribution of productivity characteristics of the nonwhite labor force relative to whites during the 1960's.

Table 2 shows that nonwhites would benefit more from having the white earnings function than the white productivity characteristics. This was true in both 1959 and 1969. The higher identical productivity *NWER* estimates in 1969 reflect the fact that the nonwhite earnings function was more similar to the white in 1969 than in 1959.

Our efforts in this section to isolate changes in relative productivity from discriminatory employment practices still suffer from a major shortcoming. If we have excluded other variables that influence earnings, our identical productivity estimates may be biased. If the excluded variables are associated with our other independent variables, they will bias our identical earnings function estimates. We would like to be able to "hold more things constant" and we will attempt to accomplish this objective in the following section.

V. Cohort Analysis

In attempting to analyze the effects of improving employment opportunities and changes in labor force characteristics, there are several advantages of using cohort data—data for the same age group at different points in time. First, comparison problems associated with the lifecycle pattern of earnings or changes in the lifecycle pattern are minimized. Cohort analysis allows one to measure the earnings of both whites and nonwhites at a similar point in their cycle of lifetime earnings.

Second, cohort comparison enables the investigator to hold "earnings related variables" constant over time. The data allow us to adjust in both 1960 and 1970 for factors such as rural, marital, and veteran status, southern residence, years of schooling, and hours worked. But we are unable to adjust directly for other factors such as health, achievement, motivation, and job preferences that might influence the current white-nonwhite earnings differential. Although there are racial differences in these and other earnings related variables, there is little reason to expect that such differences for adult age cohorts will change significantly over time.[9]

A third advantage of using cohort data is that it will allow us to say something about *changes* in the white-nonwhite differential in employment opportunities and economic preparedness of successive age groupings. Does each age group have the same opportunity as their predecessors ten years earlier? Or have changes taken

---

[8] The identical earnings function estimates are:

$$\frac{Y_w(P_n)}{Y_w(P_w)} \text{ and } \frac{Y_n(P_n)}{Y_n(P_w)}$$

where the former estimate assumes that both whites and nonwhites received the white earnings function payoff. The latter estimate assumes that both groups received the nonwhite earnings function payoff.

[9] A sample cohort of persons is drawn from basically the *same population* at two different points in time. Therefore, since the sample cohort is representative of the same population, we can expect a constancy of racial differences for many variables that are not directly included in our model.

place over time that allow successive generations different opportunities? The cohort comparison is particularly well suited to analyzing these types of questions.

VI. Cohort Changes

Utilizing the Public Use Sample data, files were created for the following age groupings: males 25–34, 35–44, and 45–54 in 1960 and males 35–44, 45–54, and 55–64 in 1970. By pairing these age groupings, it is possible to compare three age cohorts of adults during the 1960's. During the decade, the *NWER* within cohort groupings increased between 5.1 and 7.3 percent as illustrated in Table 3. These gains were considerably smaller than the 14.4 percent increase in the *NWER* estimated for all males.

The separate earnings approach of Section IV was also used to adjust the *NWER* for differences in productivity and earnings function within cohorts. We followed the same procedure as outlined above for the separate earnings approach, adjusting for the same seven factors. If both whites and nonwhites were assumed to have the white productivity mean values, the estimated adjusted *NWERs* in 1959 were 73.7, 70.8, and 65.1 percent for males of ages 25–34, 35–44, and 45–54, respectively. By 1969 the parallel estimates for the same cohorts groupings were 77.9, 74.0, and 70.6 percent, an average gain of 6.0 percent during the decade. Changes in the identical productivity estimates reflect only relative changes in the earnings functions, because productivity is held constant. Since these estimates are for cohorts, we are also holding several other factors relatively constant, even though they are not directly included in our model. The results imply that nonwhites of similar productivity as whites found their relative earnings increasing by approximately 6.0 percent during the 1960's. This is lower than our previous estimate, using the separate earnings approach, when males of all age groups were included. It probably reflects the greater similarity of the excluded factors for the cohort groupings.

TABLE 3—ESTIMATED CHANGES IN THE *NWER* WITHIN COHORT GROUPINGS BETWEEN 1959 AND 1969[a]

Cohort Group	1959	1969	Change
Actual *NWER*			
25–34 in 1960 (35–44 in 1970)	60.6	65.0	+7.3
35–44 in 1960 (45–54 in 1970)	56.8	60.3	+6.2
45–54 in 1960 (54–64 in 1970)	53.2	55.9	+5.1
Unweighted Mean	56.9	60.4	+6.2
Hypothetical *NWER*—Separate Earnings Approach			
Identical Productivity (white)			
25–35 in 1960	73.7	77.9	+5.7
35–44 in 1960	70.8	74.0	+4.5
45–54 in 1960	65.1	70.6	+8.4
Unweighted Mean	69.9	74.1	+6.0
Identical Earnings Function (white)			
25–34 in 1960	80.4	83.3	+3.6
35–44 in 1960	76.3	75.6	−1.0
45–54 in 1960	69.7	72.5	+4.0
Unweighted Mean	75.5	77.1	+2.1

Source: See Table 1.

[a] Shown in percent.

The identical earnings function estimates reflecting only changes in the amount of productivity factors possessed are also presented in Table 3 according to cohort. As would be expected, within adult cohorts, the estimates indicate that relative changes in mean productivity levels were small. The *NWERs* using the unweighted means for the identical earnings function estimates were 75.5 percent in 1959 and 77.1 percent in 1969, a gain of only 2.1 during the decade.

Table 3 yields considerable insight into the mechanism that brought about the relative earnings gains of nonwhites during the 1960's. The increase in the *NWER* within cohorts during the 1960's was much smaller—less than half of the total aggregated gains of nonwhite males. And the *NWER*, both unadjusted and adjusted for relative productivity differences, is negatively associated with age. The younger the age grouping, the higher the *NWER*. This is an important factor in explaining the magnitude of the gains in the *NWER* for all males in the total population during the 1960's. Older nonwhites with the lowest earnings relative to whites of corresponding age exited from the labor force and were replaced by younger nonwhites, who are better prepared for the labor market. This mechanism, the exiting of the older group and the entry of the younger group, accounted for approximately one half of the 14.4 percent gain during the decade.

VII. Educational Payoffs Within Cohort Groups

Past researchers have noted racial differences in the earnings payoff derived from schooling.[10] The education-earnings relation is particularly important since it not only directly influences economic status, but it also will influence the incentive to acquire human capital. Table 4 summarizes the earning payoffs from schooling for cohort groups. Two aspects of the estimates stand out. First, the relative education earnings payoff is definitely negatively related to age.[11] The older age groupings have lower *NW/W* education-earnings payoffs. In both 1959 and 1969, the relative payoffs of nonwhites 45–54 in 1960 were less than half the payoff for their "sons" in the 25–34 (in 1960) grouping. Second, while there was wide variance in the education-earnings payoff among age groupings, there was little change *within a cohort* during the 1960's. For instance, the relative marginal earnings per unit of education for nonwhites 25–34 in 1960 was 53.4 percent of whites in 1959 and 59.5 percent in 1969.

TABLE 4—THE ESTIMATED INDEPENDENT IMPACT OF A YEAR OF SCHOOLING ON THE EARNINGS OF WHITE AND NONWHITE MALES ACCORDING TO COHORT AND YEAR

	Estimated Change in Earnings Per Year of Schooling[a]		
Year and Cohort	Nonwhite[b]	White[b]	*NW/W*[c]
1959			
25–34 in 1960	$137	$257	53.3
35–44 in 1960	182	463	39.3
45–54 in 1960	104	444	21.1
1969			
25–34 in 1960	$388	$649	59.8
35–44 in 1960	320	741	43.2
45–54 in 1960	178	636	28.0

Source: See Table 1.

[a] These estimates of the coefficient of the schooling variable are for a model that includes rural status, southern residence, veteran status, marital status, and hours worked in addition to the schooling variable. The model was run separately according to color and age group for both 1959 and 1969.

[b] Shown in 1969 dollars.

[c] Shown in percent.

This result indicates that each successive cohort of nonwhites receives a higher earnings payoff from schooling than their predecessors. However, once the cohort is in the labor market there is little change in the relative payoff. There are a number of factors that might help explain this phenomenon. First, if achievement differences contribute to the lower educational payoff of nonwhites, the pattern of the payoffs over time implies that these differences according to color are declining. Perhaps this reflects the relative improvement in the quality of black schooling. Second, older nonwhites may have a lower earnings-education payoff (and a lower *NWER*) because of greater discrimination in past employment practices. The nonwhite high school graduate who was channeled into menial, low skill jobs by the employment practices of 10 to 20 years ago can never really make up this loss, even if current practices are less discriminatory.

---

[10] For example, see Freeman, Welch, Bergmann and Lyle, Harrison, Giora Hanoch, Gwartney, Dave O'Neill, Leonard Weiss and Jeffrey Williamson, C. Haworth and David Rasmussen, and R. Weiss.

[11] This result is consistent with the findings of Finis Welch, who concluded that the earnings payoff from school was negatively related to experience.

Taken together the cohort analysis of relative earnings and the earnings-education payoff strongly imply that (a) there has been a substantial improvement in the relative labor market preparedness of successive cohorts of nonwhite males, and/or (b) the discrimination of past employment practices is continuing to exert a substantial impact on current earnings according to color.

VIII. Analysis According to Educational Groups

Analysis of the relative earnings of separated educational groupings may shed light on structural changes in employment opportunities. Others have argued that employment discrimination is strongest at the very top of the job hierarchy and thus employment discrimination is strongest against the best educated blacks.[12] This hypothesis implies that the adjusted *NWER* and relative marginal payoffs to education would be lowest for blacks with the most education.

Table 5 presents evidence on the adjusted *NWER* within the three educational groupings by region and for younger persons. In 1959, the adjusted *NWER* was highest for the least educated and lowest for those with the most education. This pattern of the adjusted *NWER* is highly consistent with the "pattern of employment discrimination" theory.[13] In 1969, this was much less the case. During the 1960's, the largest gains in the adjusted *NWER* were recorded by the best educated. In the North, the adjusted *NWER* for males with 0–10 years of education increased by 1.8 percent. Similar small relative gains were recorded by the poorly educated in the South and by younger persons with little schooling. By contrast, the estimated adjusted *NWER* ratio for nonwhite males with 14 or more years of schooling increased by 15.3 percent in the North, and 13.9 percent in the South. The relative increase in the *NWER* for those with 11–13 years of schooling also exceeded those of the poorly educated group.

Table 5—The Adjusted *NWER* for Males with 0–10, 11–13, and 14+ Years of Schooling According to Region and for Persons Age 14–34 for 1959 and 1969

Group by Years of Schooling		Adjusted *NW/W* Earnings Ratio[a] 1959	1969	Change
Non-South	0–10	82.8	84.3	+ 1.8
	11–13	76.7	82.3	+ 7.3
	14+	72.4	82.5	+15.3
South	0–10	72.6	74.3	+ 2.3
	11–13	64.5	74.0	+14.7
	14+	61.0	69.5	+13.9
Persons: Ages 14–34				
	0–10	83.3	86.3	+ 3.6
	11–13	76.3	86.0	+12.7
	14+	77.3	85.3	+10.3

Source: See Table 1.

[a] The aggregated earnings approach was utilized to adjust for years of schooling, age, marital status, rural status, region, hours worked, and veteran status. Ratios shown in percent.

When only younger earners—persons age 14 to 34—are considered, the negative relation between education and the adjusted *NWER* had evaporated completely by 1969. The adjusted *NWER* for all three educational groupings was approximately 86 percent. These findings indicate that structural changes in employment opportunities during the decade reduced the strength of the pattern of discrimination hypothesis.

The *NW/W* marginal payoffs per year of schooling for persons age 14–34 within educational groupings are shown in the following tabulation for the estimated adjusted additional earnings per year of schooling:

---

[12] For example, see Harrison and Siegel.

[13] Of course, other factors such as a widening achievement gap as quantity of schooling increases may also explain this pattern of the *NWER*.

		Nonwhite	White	*NW/W*
1959	0–10	$ 49	$117	.42
	11–13	$122	$237	.51
	14+	$349	$133	2.62
1969	0–10	$ 43	$ 73	.59
	11–13	$376	$294	1.28
	14+	$362	$393	.92

Except for those with 0–10 years of schooling, the adjusted marginal payoffs from additional schooling were similar according to color in 1969. These data are also consistent with a weakening of the pattern of discrimination hypothesis during the 1960's. The pattern of discrimination theory has sometimes been used to argue that it was "rational" for nonwhites to become "school dropouts." The data presented in this section suggest that as of 1969, white and black males with 11 or more years of schooling had a similar monetary incentive to *continue* on to a high school or college degree.

IX. Summary and Conclusions

The aggregate increase in the *NWER* during the 1960's stemmed from two major sources. First, the *NWER* increased an estimated 6.0 percent because nonwhite males were able to improve the relative payoff derived from their productivity factors. This gain would reflect primarily improved employment opportunities and a decline in employment discrimination against blacks. In addition, approximately 2 percent is estimated to stem from gains in the amounts of productivity factors possessed by nonwhites relative to whites. A second major source of change—accounting for gains of between 6 and 8 percent in the *NWER* during the decade—was attributable to the exiting of older nonwhite workers with low relative earnings combined with the entry of younger, better-prepared nonwhites who have high relative earnings.

A consistent negative relationship exists between age and the *NW/W* education-earnings payoff. While successive cohorts of younger black males receive a greater relative payoff from their schooling, the estimated *NW/W* earnings per year of schooling within cohort groupings increased only slightly during the decade.

There is evidence that important structural changes in employment opportunities took place during the 1960's. The largest gains in relative earnings were recorded by those with the most education. The *NWER* for persons with 14 or more years of schooling increased 15.3 percent in the North and 13.9 percent in the South. A similar pattern of earnings gains was recorded by younger people. In addition, the relative payoffs from continuing in school were greater for the better educated. By 1970, the *additional* earnings per year of schooling for younger (under 35) nonwhite males with 11 or more years of schooling were very similar to whites. The disincentive of nonwhites to continue past the tenth grade caused by low marginal payoffs to education was sharply reduced during the decade. Thus, while the aggregated data overstate the earnings gains attributable to improved employment opportunities, they also fail to reveal important structural changes in relative earnings. The structure of the changes, for both the *NWER* and the payoffs from additional schooling, suggests that progress was made during the 1960's toward breaking the cycle of poverty resulting from discriminatory employment practices.

Direct Measurement of Popular Price Expectations

By GEORGE DE MENIL AND SURJIT S. BHALLA*

Expectations are an important determinant of economic behavior. The analysis of economic expectations, however, has suffered from inadequate measurement. Throughout the literature, expectations have been treated as unobservable, and have therefore been measured only indirectly. The object of this paper is to develop and test a direct measure of the expectations of inflation, a particularly critical economic variable.

A direct measure of inflationary expectations is here taken to be one constructed from a sample survey in which individuals are asked to state their expectations explicitly. The paper focuses on a popular forecast of the rate of change of consumer prices in the forthcoming year as calculated from responses to the *Survey of Consumer Finances* (*SCF*). This measure is presented in Section I.

The *SCF* and others like it have existed for some time, but, a few recent studies notwithstanding, most economists continue to regard survey measures as inherently unreliable.[1] Their principal criticism is that the opinions an individual expresses in an interview are not the same as the opinions on which he acts. At issue in this criticism is whether direct or indirect measures of expectations can best explain actual behavior. Tests of the explanatory power of the direct measure of expected inflation developed in Section I are presented in Sections II and III. The results demonstrate that the *SCF* measure of expected inflation, particularly when combined with a related measure of unexpected inflation, explains wage increases better than several currently used indirect measures. In particular, when the *SCF* measures are added to the wage equations of George Perry, Otto Eckstein and Roger Brinner, and Robert Gordon (1971), they perform better than these authors' own indirect measures in the first two cases, and as well as the indirect measure used in the third case.

I. Price Expectations in the *Survey of Consumer Finances*

The *Survey of Consumer Finances* is a survey of a representative sample of *U.S.* households conducted every year by the Survey Research Center of the University of Michigan. (See the Appendix for details.)

One of the questions asked in almost every survey has been the following:[2]

---

* Assistant professor of economics and graduate student, respectively, Princeton University. We are grateful for the comments of Robert Solow, Paul Wachtel, and the referee. Part of our research was supported by the National Science Foundation.

[1] The responses to questions regarding inflationary expectations in the *SCF* have not been widely used. The exceptions are the reports of the Michigan Survey Research Center and the consumption studies of Eva Mueller, Thomas Juster and Paul Wachtel (whose study in the *Brookings Papers* uses a measure similar to the one developed here), and Lester Taylor. One survey measure of price expectations which has attracted attention recently is the biannual survey of business economists conducted since 1947 by Joseph A. Livingston, one-time financial editor of the *Philadelphia Bulletin*. The Livingston measure has been analyzed by Stephen Turnovsky, and has been used in wage studies by Robert Gordon and by Turnovsky and Michael Wachter, and in interest rate studies by D. H. Pyle and William Gibson.

[2] The precise wording of the question has in fact varied from time to time, as is pointed out in the Appendix. The wording given here is that used after 1960. See *1970 Survey of Consumer Finances*, p. 257.

"Thinking about prices of things you buy in general, do you think they will go up in the next year or so, or go down, or stay where they are now?" In addition, since the second quarter of 1966, respondents expecting prices to go up have been asked: "How large a price increase do you expect? Of course nobody can know for sure, but would you say that a year from now prices will be about 1 or 2% higher, or 5%, or closer to 10% higher than now, or what?" It is possible to estimate the mean and other moments of the distribution of expectations of price change since 1966:2 from the answers to both of these questions. The critical problem, however, is how to infer similar quantitative estimates from the limited data available before 1966.

A suggestive discussion of this problem can be found in Henri Theil's analysis of the Munich Business Test in chapter 4 of *Economic Forecasts and Policy*. Theil constructs from the percentage of respondents expecting sales to rise, fall, and stay the same, a dispersion index, which he also calls the balance.

$$BAL = \frac{\%\ \text{Rise} - \%\ \text{Fall}}{\%\ \text{Rise} + \%\ \text{Fall} + \%\ \text{Same}}$$

He then discusses qualitatively the relationship between BAL and the complete distribution of forecasts. His discussion can be pushed further and applied to the problem of price expectations.

Let X be an individual respondent's expectation of the rate of price increase in the forthcoming year; let the density and cumulative distribution over the population of such expectations be, respectively, $f(X)$ and $F(X)$. Let the mean of this distribution be $EXPT$ and the standard deviation be SIG. If one takes the "stay the same" response to correspond to a prediction of some small change between $+\delta$ and $-\delta$, and if, for the sake of simplicity, one assumes these responses to be equally distributed between positive and negative changes, then

$$BAL = \int_0^\infty f(X)dX - \int_{-\infty}^0 f(X)dX$$

or

$$(1) \quad BAL = 1 - 2F(0)$$

If the shape of the distribution were known, (1) would provide a relation between BAL and $EXPT$ which could be used to estimate $EXPT$ prior to 1966:2.

The assumption maintained in this paper is that $f(X)$ is normal.[3] It then follows that

$$Z = \frac{X - EXPT}{SIG}$$

is a standard normal variate. If $G(Z)$ is its cumulative distribution then (1) may be written as

$$(1') \qquad BAL = 1 - 2G\left(\frac{-EXPT}{SIG}\right)$$

This is a relation between $EXPT/SIG$ and BAL, which, when plotted by means of the standard normal tables, is seen to pass through the origin and to be approximately linear over most of the range of BAL.[4]

The following linear approximation to (1′) was estimated using post-1966:2 data for the three relevant variables.

$$(2) \qquad \frac{EXPT}{SIG} = \underset{(140.3)}{1.50}\ BAL$$

---

[3] Unfortunately, the *SCF* data themselves provide no way to test this assumption. Answers to the quantitative question asked since 1966:2 were coded in five intervals (see Appendix). These answers, however, cluster in the three intervals 1–2 percent, 5 percent, and 10 percent or more, and this makes it impossible to use them to test for the shape of the underlying distribution.

[4] BAL is both positive and negative in the post-World War II period, but its absolute value is rarely greater than .85.

period of fit: 1966:2–1972:3,[5] with omissions

$$R^2 = .922 \qquad \text{D.W.} = 1.812$$

Equation (2) could permit backwards extrapolation of *EXPT* if *SIG* were known. But, like *EXPT* itself, *SIG* can only be measured directly after 1966:2. Therefore an attempt was made to derive an equation for *SIG* using the post-1966:2 data. The plot of *SIG* revealed a modest rise between 1966 and 1968 from 2.5 to 2.6 followed by a sharp increase to 3.0 in 1969 and 1970. A plausible interpretation of this pattern is that it reflects a tendency for the standard deviation to rise as the mean rises plus an increase in popular uncertainty about the future course of prices in the first two years of the Nixon Administration, when inflation and unemployment were both increasing at the same time. In order to test this hypothesis it was decided to regress *SIG* after 1966:2 against *EXPT* and an index of popular uncertainty about economic conditions. The index chosen, with some reservations, was the Index of Consumer Sentiment, an average of dispersion indices based on five attitudinal questions in the *SCF*. Though these questions ask about optimism and pessimism concerning economic conditions, there is also some basis for treating the Index as a measure of uncertainty.[6]

In line with the preceding discussion, the following equation was estimated.[7]

$$(3)\quad \underset{(17.1)}{SIG = 3.56} + \underset{(4.30)}{.20EXPT} - \underset{(-15.6)}{.018MOOD}$$

period of fit: 1966:3–1971:2, with omissions

$$R^2 = .968 \qquad \text{D.W.} = 1.89$$

MOOD is the Index of Consumer Sentiment. Combining (2) and (3) one obtains the following equation for backwards prediction of *EXPT*:[8]

$$(4)\quad EXPT = \frac{\underset{(17.0)}{5.35BAL} - \underset{(-15.6)}{.027MOOD\cdot BAL}}{1 - \underset{(4.27)}{.30BAL}}$$

This equation was used to calculate values for *EXPT* from 1952:4 through 1966:1, which were then combined with the measure of *EXPT* taken directly from the *SCF* from 1966:2 through 1972:3. Details of data construction are discussed in the Appendix.[9]

The series for *EXPT* thus constructed remains a crude measure of inflationary expectations. Because of its heavy reliance on the balance, which is only a summary statistic, the measure ignores some of the information contained in the responses, and in fact may be biased.[10] Despite these recognized drawbacks, the balance statistic has featured prominently in most empirical work on surveys to date. Moreover, even if it is biased, *EXPT* may still be a better measure of inflationary expectations than the indirect measures used in most empirical work. The next section reports the results of tests comparing *EXPT* with alternative indirect measures.

---

[5] *EXPT* and *SIG* were estimated from the quantitative estimates of expected inflation. The omissions refer to the quarters (1966:4, 1967:2, and 1968:1) for which such data were not available. (*T*-statistic in parentheses.)

[6] A recent important study on consumption by Juster and Wachtel (1972a, b) treats the Index as a measure of uncertainty. Also, Dwight Jaffee reported finding that the spread between BAA and AAA bonds of the same type of issuer and maturity was highly negatively correlated with the Index of Consumer Sentiment.

[7] In order to adjust for negative serial correlation, equation (3) was estimated using two-quarter averages of all variables. Regarding the omitted observations, see fn. 5. The sample period here stops short of the Phase 1 and Phase 2 controls of the Nixon Administration because of the presumption that the controls may have caused structural change in the degree of uncertainty associated with price expectations.

[8] Each coefficient in equation (4) is the product of coefficients in (2) and (3). Each variance was estimated as the variance of the linear terms of the Taylor's series approximation to the product. The *t*-statistic in parentheses under the coefficient is based on that estimated variance.

[9] It was felt that, the arguments in the text notwithstanding, some uncertainty remains regarding the proper interpretation of *MOOD*, and consequently regarding the validity of equation (3) and the related equation (4). Therefore, an alternative measure of *EXPT* was constructed based on the assumption that prior to 1966:2, *SIG* was a constant equal to its average value from 1966:2 to 1968:4. All of the experiments reported in Sections II and III were also conducted with this alternative measure. As it turned out, both of the series and the results of the tests based on them were very similar. When compared with its sharp movement in 1969–70, the entire previous history of *MOOD* back to the first observation in 1952:4 is relatively stable. Therefore the behavior of an *EXPT* series based on *MOOD* is quite similar to that of an *EXPT* series based on the assumption of a constant *SIG*.

II. Competing Measures

As explained earlier, it was decided to test the validity of *EXPT* by comparing its ability to explain wage increases with that of the indirect measures used in three recent equations which were the subject of a comparative study by Gordon (1972).[11] The equations—by Perry, Eckstein and Brinner, and Gordon (1971)—were selected because of the convenience of Gordon's comparative study and because in two of these three equations, particular emphasis had been placed on the specification of the price expectations variable.

In the three test equations, as in most work on economic expectations, expected price change is assumed to be a function of past rates of actual price change. Perry's specification of expected price change is the simplest, namely that it is equal to the quarterly rate of change of the consumer price index, lagged one quarter. Eckstein and Brinner lengthen somewhat the distributed lag on past price changes and add an additional threshold effect.[12] Their distributed lag spans the full year prior to the current quarter, and has weights which decline linearly to zero. Their threshold level is 2.5 percent annual inflation, and their additional expectation variable is the positive excess over the threshold of the annual rate of inflation during the two previous years. Gordon's specification is the most complex. His expectations variable is a twelve-quarters long, freely estimated, polynomial, distributed lag on the quarterly rate of change of the deflator for personal consumption expenditures. In addition, he introduces another price variable to represent the short-run effect of product demand on labor, namely an eight-quarter polynomial distributed lag function of the difference between the rate of change of the deflator for private nonfarm *GNP* and the personal consumption deflator. Conceptually this is not an expectations variable, but it is clear that statistically it may be correlated with expectations variables.

All three of these indirect representations of inflationary expectations are quite different from *EXPT*, as evidenced by their low correlations with *EXPT* (Perry, 0.69; Eckstein and Brinner, 0.59; Gordon, 0.60).[13]

The balance of the specification of each of the test equations is described in the studies cited above, including Gordon's comparative study.

---

[10] The balance statistic is constructed in such a way as to be roughly invariant to changes in the percentage of respondents saying "stay the same." A more refined method for inferring the mean expectation from responses to a question about the direction of change has been used by Harry Shufford, John Carlson and Michael Parkin, and de Menil. The statistical properties of the measure used in these studies have been analyzed in depth by Carlson and Harl Ryder.

[11] Gordon kindly supplied us with his complete data base.

[12] They also, as does Gordon, replace the consumer price index with the deflator for personal consumption expenditures.

[13] These correlations refer to the period 1954:1–1971:2. The Eckstein-Brinner measure is taken to be the weighted average of their distributed lag variable and their threshold variable with the weights based on the coefficients of these variables in the two-quarter estimate of their original equation.

Gordon's estimation procedure, which is followed here, is to estimate each equation in both one-quarter and two-quarter form. In the one-quarter form, the dependent variable is a one-quarter rate of change of the wage rate at an annual rate, and all independent variables are either one-quarter rates of change at an annual rate or one-quarter averages of level variables, or distributed lag functions of either of these. The two-quarter form is simply a two-quarter average of both the left- and right-hand sides of the one-quarter equation.

Gordon's estimates of the original three test equations for the period 1954:1–1970:4 appear in column 1 of Tables 1, 2, and 3.[14] In each block of the column, the two-quarter estimate and its t-statistic are presented above the corresponding one-quarter estimate. Precise variable definitions appear in the glossary accompanying each table.[15]

III. Significance Tests

Expected inflation influences wage change in a very simple manner in each of the three test equations. An increase in expected inflation results in a fractional increase in wage change in the following quarter. The availability of a direct measure such as ours permits a more complex modeling of the impact of expectations. One hypothesis, originally advanced by Stephen Turnovsky and Michael Wachter, is that in addition to the initial impact, there is a "catch-up" effect whereby wages catch up with a portion of the difference between recent inflation and previous expectations.

This effect is difficult to represent if one's measure of expectations is itself based on recent inflation. But with a direct measure like $EXPT$, the effect can readily be represented by the difference between recent inflation and an appropriate past value of $EXPT$. Reasoning that unexpected inflation influences wage change through increasing worker demands in new contract negotiations, and activating escalator clauses, we maintain that it is the average amount of unexpected inflation over the past year which is relevant[16] and, therefore, that the catch-up effect may be represented by $CATCH$, where

$$CATCH = \overset{4}{g_d} - \overline{EXPT}_{-4} \tag{5}$$

In this expression, g_d^4 is the four-quarter rate of change of the deflator for consumer expenditures d; $\overline{EXPT}_{-4}$ is the average of $EXPT$ four and three quarters ago. This average is used in place of $EXPT$ itself in order to remove some of the purely random variability of the series.

In view of the above, two tests were performed with each of the selected equations. The first was a simple comparison of

---

[14] Our estimates of the equation in col. 1 of Table 3 differ slightly from Gordon's because, unlike Gordon, we were unable to constrain the first derivatives of the polynomial lags to be zero in the furthest period. The differences, however, are small, and all our other benchmark results agree exactly with Gordon's.

[15] In addition to the variables listed in Tables 1, 2, and 3, each of the original equations has one or more different personal and/or social security tax variables. All of these variables are highly orthogonal to the other independent variables and their estimated coefficients are quite insensitive to changes in the other independent variables; therefore we have excluded these coefficients from our tables.

[16] The average duration of union contracts is about three years and has not changed much between 1954 and 1970. See Cornelia Ward (1959, 1965), and M. E. Sparrough and L. W. Bolton. There is less evidence on the frequency of wage adjustments in nonunion employment, but the norm appears to be one year. If union contracts are given a weight of .2 and nonunion wage adjustments a weight of .8, a rough estimate of 1.4 years is obtained for the average time span between wage decisions in the private economy. In order to allow for the existence of escalator clauses which can be activated quarterly, this estimate was adjusted downward to one year. The differences in the results with an alternative, six-quarter specification of the catch-up effect turned out to be marginal.

TABLE 1—PERRY WAGE EQUATION

Variable	Original Equation	*EXPT* Added	*EXPT* and *CATCH* Added	Perry's Expectations Excluded

Source: See Gordon, *Brookings Papers*, 2:1972.

Notes: Estimated coefficients for two-quarter equations (with their absolute *t*-statistics in parentheses) appear in the top half of each row; estimates (and *t*-statistics) for one-quarter equations appear in the bottom half. The sample period for all equations is 1954:1–1970:4.

Definitions given for one-quarter equations. Variables in the two-quarter equations are all two-quarter averages of the corresponding variable in the one-quarter equations. The symbol g_x represents the quarterly rate of increase of the variable X at an annual rate, and $g_{x_{-\tau}}$ the same quarterly rate of increase lagged τ quarters.

g_w = the dependent variable: W is an hourly earnings index for production workers in the private nonfarm economy, adjusted for overtime and changes in interindustry mix. The index has further been adjusted to include fringe benefits. (See Gordon (1972).)

U^* = Weighted unemployment rate. (See Perry (1970).)

DU = Unemployment dispersion index. (See Perry (1970).)

D_G = Guidepost dummy. Set equal to 0.25 in 1962:1, 0.50 in 1962:2, 0.75 in 1962:3, 1.0 in 1962:4 to 1966:4, 0.75 in 1967:1, 0.50 in 1967:2, 0.25 in 1967:3, and 0.0 in other periods.

C = Consumer Price Index.

$EXPT$ = Annual rate of inflation expected, forthcoming year *SCF*. See Appendix.

$CATCH$ = Unexpected inflation during preceding year, at annual rate, *SCF*. See equation (5).

Source and general notes: See Table 1.

Variable Definitions:

g_W = Dependent variable. Same as Table 1.

U = Conventional unemployment rate.

D_G = Guidepost dummy. Same as Table 1.

d = Personal consumption deflator.

g_d^* = Expected inflation variable with imposed weights: $g_d^* = 0.4\, g_{d-1} + 0.3 g_{d-2} + 0.2 g_{d-3} + 0.1 g_{d-4}$. (See Gordon (1972).)

g_d^T = Threshold inflation variable $= 0.0$ if $[(d_{-1} - d_{-5})/d_{-5}] \leq 0.05$; otherwise $= \frac{1}{2}[d_{-1} - d_{-5}/d_{-5} - 0.05]$. (See Eckstein-Brinner (1972) and Gordon (1972).)

EXPT = Same as Table 1.

CATCH = Same as Table 1.

the explanatory power of *EXPT* and the given, indirect measure of expected inflation on the assumption that there is no catch-up effect. This test consisted of adding $EXPT_{-1}$ to the original equation.[17] The second test was a test of the joint hypothesis that *EXPT* is the better measure of expectations and that there is a catch-up effect. It consisted of adding $EXPT_{-1}$ and $CATCH_{-1}$ to the original equation. Since the two hypotheses just mentioned interact, it is quite possible that $EXPT_{-1}$ may fail the first test even though $EXPT_{-1}$ and $CATCH_{-1}$ together pass the second one. This in fact occurred in one case.

---

[17] The one-quarter lag allows for a response delay and parallels the lag specification in Gordon's comparative study.

The a priori ranges for values of the coefficients of $EXPT_{-1}$ and $CATCH_{-1}$ are both between 0 and 1, though there is no a priori restriction on which of the two should be larger. The results obtained are reported in columns 2, 3, and 4 of Tables 1, 2, and 3. Columns 2 and 3 report coefficient estimates when $EXPT_{-1}$ and both $EXPT_{-1}$ and $CATCH_{-1}$ were added to the original equation. Column 4 presents coefficients estimates when the original expected inflation variables were dropped and $EXPT_{-1}$ and $CATCH_{-1}$ took their place.

In Perry's equation, $EXPT_{-1}$ was not significant when entered alone (Table 1, col. 2).[18] However, both $EXPT_{-1}$ and $CATCH_{-1}$ were significant and Perry's rate of change of the consumer price index was not when the two *SCF* variables were entered together (Table 1, col. 3). The superiority of the latter equation to Perry's original equation clearly supports the two *SCF* variables.

When $EXPT_{-1}$ was entered alone in the Eckstein-Brinner equation, both g_d^*, the distributed lag measure, and $EXPT_{-1}$ were significant in the two-quarter estimate, and neither were in the one-quarter estimate (Table 2, col. 2). The threshold variable g_d^T remained significant in these and all estimates for the sample period extending through 1970:4.

Again, a clearer verdict was obtained when the two *SCF* measures were entered together (Table 2, col. 3). Both $EXPT_{-1}$ and $CATCH_{-1}$ were then individually significant in the two-quarter estimate and $EXPT_{-1}$ was significant and $CATCH_{-1}$ barely missed significance in the one-quarter estimate. By contrast, the Eckstein-Brinner distributed lag variable was insignificant in both estimates. This left the threshold variable g_d^T as the only significant Eckstein-Brinner variable. When additional evidence concerning instability of the coefficient of g_d^T is considered, the verdict that emerges is one favorable to the *SCF* variables.

Except for a brief period in 1957–58, the threshlod variable is only positive during the high inflation period of the late 1960's and early 1970's. Not surprisingly, its coefficient in the original Eckstein-Brinner equation was not significant for shorter sample periods tested (1954:1–1966:4, 1954:1–1968:4). In fact, when the equation in Table 2, column 3, was re-estimated for those sample periods, g_d^T was never significant and g_d^* was only significant in the two-quarter equations, whereas $EXPT_{-1}$ was significant in all equations and $CATCH_{-1}$ in the two-quarter equations. Moreover, in those shorter sample periods, all estimates of the equation with only *SCF* variables had lower standard errors than the corresponding estimates of the original Eckstein-Brinner equation. In short, when the evidence from all three sample periods is considered together, it supports the *SCF* variables rather than the Eckstein-Brinner variables.

The tests performed with Gordon's equation resulted in a standoff between the *SCF* variables and Gordon's expected inflation variable. When $EXPT_{-1}$ was entered alone, both it and Gordon's distributed lag measure, g_d^e, were significant in two-quarter and one-quarter estimates (Table 3, col. 2).[19] When $CATCH_{-1}$ was

---

[18] Unless otherwise indicated, an individual coefficient will be said to be significant if it passes a one-tailed t-test at the 10 percent level, and a group of coefficients will be said to be all significantly different from zero if they pass the appropriate F-test at the 10 percent level.

[19] Gordon in fact uses four variables to estimate the distributed lag in g_d^e. Therefore, the appropriate test of the hypothesis that not all of these coefficients are equal to zero is an F-test of the reduction of variance due to

(over to p. 178)

Source and general notes: See Table 1.

Variable Definitions:

g_W = Dependent variable. Same as Table 1; *DU* = Same as Table 1.

U^D = Disguised unemployment rate; U^H = Unemployment rate of hours. (See Gordon (1972).)

d = Personal consumption deflator.

g_d^e = Distributed lag on the quarterly rate of change of the personal consumption deflator, with weights estimated as a polynomial distributed lag, starting in t−1, with individual coefficients constrained to lie along a fourth degree polynomial with level set equal to zero in the most distant period (t−12). The coefficients in the table are the sum of the estimated weights. The numbers in parentheses are the ratio of this sum to its standard error.

$(g_p - g_d)$ = Distributed lag on the difference between the quarterly rate of change of p, the private nonfarm deflator, and the quarterly rate of change of d, starting in t−1, with individual coefficients constrained to lie along a third degree polynomial and set equal to zero in the most distant period (t−7). The coefficients are sums of estimated weights, and each number in parentheses is the ratio of this sum to its standard error.

EXPT = Same as Table 1; *CATCH* = Same as Table 1.

added, the two-quarter estimate favored Gordon's variable while the one-quarter favored the *SCF* variables,[20] and judgment was again left in balance.[21]

In summary, if one views the tests performed on all the equations as a whole, the evidence supports both the inclusion of *EXPT* as an explanatory variable and the contention that there is a catch-up effect. This effect has interesting policy implications which can be best presented by decomposing *CATCH* into its parts and then rearranging the terms as follows:

$$\begin{aligned}(6)\quad \gamma\, EXPT_{-1} + \lambda\, CATCH_{-1} &= \lambda\, g^4_{d_{-1}} + (\gamma - \lambda) EXPT_{-1} \\ &\quad + \lambda\,(EXPT_{-1} - \overline{EXPT}_{-5})\end{aligned}$$

It is immediately clear that expected inflation is not the only feedback from prices to wages. Recent inflation, as represented by g^4_d, also influences wage increases. In fact, if $\gamma=\lambda$, a hypothesis which cannot be rejected in any of the estimates in column 4 of the three tables, the effect of expected inflation is only a transient one. Consequently, policy makers considering measures to reduce the rate of wage increase must consider the effects on unexpected as well as expected inflation. Pronouncements designed to bring down inflationary expectations—of which there have been many in the United States recently—may have little lasting effect if they do not also reduce actual inflation.

These tests also provide admittedly limited evidence concerning the stability of the tradeoff between inflation and unemployment. If all inflation were anticipated, *CATCH* would equal zero, and therefore, the existence of a tradeoff would depend solely on the magnitude of the coefficient of *EXPT*. In the estimates reported in column 4 of each table, this coefficient lies between .3 and .7 and is always significantly different from one. However, no allowance has been made in these estimates for the possibility that *EXPT* may be subject to measurement error, and that the estimates may consequently be biased downwards. Moreover, the sensitivity of wages to expected inflation under conditions of steady, anticipated inflation might well differ from their sensitivity in a period like that after the Korean War when even the expected rate of inflation was subject to considerable variation.

IV. Conclusion

The tests performed in Sections II and III demonstrate that the direct measures of expected and unexpected inflation developed here using responses to the *Survey of Consumer Finances* explain wage changes as well as or better than the indirect measures used in three recent studies. The significance of this result lies in its implication for our understanding of expectations. As the correlations in Section II indicate, the *SCF* measure of expected inflation differs greatly from the indirect measures of Perry, Eckstein and Brinner, and Gordon. If the *SCF* measure is correct, the other measures must be incorrect. But that observation constitutes a damning judgment, since the other measures represent the current state of knowledge regarding expectations of inflation.

---

those four variables jointly. The appropriate test of the hypothesis that the sum of the coefficients is positive is a one-tailed *t*-test based on the ratio of that sum to its standard error. In Table 3, col. 2, g_d^2 passes both the *F*-test and the *t*-test. (Only the *t*-statistic is reported in the table).

[20] In the two-quarter estimate, the *SCF* variables both have the wrong sign and Gordon's expected inflation variable passes both the *F*-test and the *t*-test. In the one-quarter estimate, however, $EXPT_{-1}$ is significant, and Gordon's variable passes the *F*-test, but not the *t*-test.

[21] Results for sample periods beginning in 1966:4 and 1968:4 were very similar, and do not alter this standoff decision.

Such a judgment leads one to seek a better understanding of expectations. Though that endeavor will be the subject of another study, hopefully this paper will have provided some of the data needed to extend the knowledge of expectations beyond the limited state to which it has been confined by the deficiencies of indirect measurement.

APPENDIX

The *Survey of Consumer Finances* (*SCF*), administered by the Survey Research Center, University of Michigan, is a survey of a representative sample of *U.S.* households, numbering around 3000, and has been conducted in January or February of every year since 1946. Supplemental surveys of about half the original size were added in 1952, and since 1959 the survey and its supplements have been administered roughly on a quarterly basis. The questions asked have dealt with both demographic and financial characteristics and with attitudes about economic conditions.

A question regarding the direction of price change similar to the one quoted in Section I has been included in almost every *SCF* since the inception of the survey in 1946. Raw data on the percentage of responses by category were obtained from reports on the *SCF* in several issues of the *Federal Reserve Bulletin* for 1946 through 1952, from *Consumer Expectations*, by George Katona and Eva Mueller for 1953–56, and subsequently from 1960 *Survey of Consumer Finances* and the succeeding annual publications of the Survey Research Center. Since 1968 the annual publications of the Center have not reported separately the percentage of respondents expecting prices to stay the same, go down, and the percentage uncertain. Those data were kindly supplied to us by Jay Schmiedeskamp, director, and Evelyn Hansmire of the Survey Research Center.

The wording of the question regarding price expectations has varied from time to time. Since 1959 the wording has been as reported in Section I. From 1951 to 1959 the question asked about "prices of household items and clothing," and from 1946 to 1951 about "prices of things in general." Overlapping periods were always available when the question changed form, and the overlap was used to link the different series.

Since 1959, the survey has usually been conducted four times a year. The timing of the surveys, however, has not been consistent, nor have survey dates necessarily matched the midpoints of the calendar quarters (February 15, May 15, August 15, and November 15). Prior to 1959, the survey was taken with varying frequency during each year. Consequently, whenever data were not available, or available at off times during the year, the series, which had been linked as described above, was interpolated linearly.

The question added to the survey in May 1966 asks for quantitative estimates from those respondents who expect prices to rise. The answers to this question were used to estimate the mean and standard deviation of expected price increases, *EXPT* and *SIG*. These answers have been coded in intervals (1–2 percent, 3–4 percent, 5 percent, 10 percent or more, don't know how much).

A mean of positive expected price increases was calculated by assigning the midpoint to each interval and 10 percent to the "10 percent or more" category. By assuming that the mean thus calculated reflected the average expectation of the "don't know how much" category, and by assigning a prediction of zero to the "fall" and "same" categories, a mean was obtained for all respondents who expressed a definite opinion in their answer to the first question. The standard deviation for this class of respondents was calculated in a consistent manner. The remainder of the sample, consisting of those who either did not answer the first question or answered that they were uncertain whether prices would rise, fall, or stay the same, was assumed to be distributed as the rest of the sample. Therefore the mean and standard deviation just described were taken as referring to the entire sample.

The Index of Consumer Sentiment was

obtained from *Survey of Consumer Finances*, 1967, pp. 247–48, and 1970, p. 207. This series was linearly interpolated in the same way as the price expectation series.

Efficient and Optimal Utilization of Capital Services

By GUILLERMO A. CALVO*

In recent times there has been renewed interest in the factors determining capacity utilization in connection with the trade cycle.[1] However, little attention has been paid to the question of the *desirability* of different rates of capacity utilization. In the present paper I discuss this problem in the context of the neoclassical one-sector model when capital depreciates as a function of the intensity at which it is operated.

I. The Model

Let us call:

K_t = capital services per unit of time available at t (proportional to capital stock)

S_t = capital services per unit of time utilized at t

L_t = labor services per unit of time available at t

N_t = labor services per unit of time used at t

Y_t = output at t

C_t = consumption at t

δ_t = rate of depreciation per unit of available capital services per unit of time at t

We assume:

$$(1) \quad \frac{DL_t}{L_t} = n, \text{ exogenously given, } n > 0 \quad L_0 > 0$$

$$(2) \quad Y = F(S, N) \qquad \text{for all } S \geq 0,\ N \geq 0$$

(3)(a) F linear homogeneous, and continuous for all $S > 0$, $N > 0$

(b) $F(0, N) = 0$

(c) $F(S, 0) = 0$

(d) $\dfrac{\partial F}{\partial S} > 0$

(e) $\dfrac{\partial F}{\partial N} > 0 \qquad$ for all $S, N > 0$

(f) $\dfrac{\partial^2 F}{\partial S^2} < 0$

(g) $\dfrac{\partial^2 F}{\partial N^2} < 0$

(h) $\lim\limits_{S \to 0} \dfrac{\partial F}{\partial S} = \infty \qquad$ if $N > 0$

$$(4) \quad S_t = m_t K_t, \qquad 0 \leq m_t \leq 1$$
$$K_t \geq 0$$

$$(5) \quad 0 \leq N_t \leq L_t$$

$$(6) \quad DK_t = Y_t - C_t - \delta_t K_t, \qquad C_t \geq 0$$

Furthermore,

$$(7) \quad \delta = g(m) \qquad \text{for all } 0 \leq m < 1$$

where

(8)(a) $g(m)$ is twice-differentiable at every $0 \leq m < 1$

(b) $g'(m) \geq 0 \qquad$ for all $0 \leq m < 1$

(c) $g''(m) > 0 \qquad$ for all $0 \leq m < 1$

(d) $\lim\limits_{m \to 1} g(m) = \infty$

Restricting m to belong to the closed unit interval is equivalent to saying that capital services used are smaller than or equal to its availability and that they cannot be negative; m can be given at least two rather different economic interpretations:

---

* Assistant professor, Columbia University. The present work was completed while I was visiting professor at the Centro de Investigaciones para el Desarrollo (*C.I.D.*), Bogota, Colombia, during 1970.

[1] See Robert Lucas, and Paul Taubman and Maurice Wilkinson.

a) It can be a measure of the speed at which machines are operated per unit of time with constant labor services used per unit of time; or

b) it can measure the share of time per unit of time at which machines are operated, given a capital-labor services ratio. In other words, it may provide a model for the choice of the number of shifts, when the ratio of factor services is the same for every shift.

The latter is perhaps better understood if we define $\overline{N}(K, mK/N)$ as the flow of labor services required to operate capital at full capacity, i.e., when $S=K$, with capital-labor services ratio equal to mK/N. Clearly, then,

$$\frac{K}{\overline{N}\left(K, \frac{mK}{N}\right)} = \frac{mK}{N}$$

and, hence,

$$m\overline{N} = N$$

Therefore, recalling (3a), output when total capital services are K and the factor services ratio equals mK/N becomes

$$F\left(mK, m\overline{N}\left(K, \frac{mK}{N}\right)\right) = mF\left(K, \overline{N}\left(K, \frac{mK}{N}\right)\right)$$

where in view of our previous definitions, $F(K, \overline{N})$ is the full capacity output when the factor services ratio equals mK/N and the total supply of capital services is K. So m can be conceived as the share of the maximum output obtained when machines are operated m parts of a unit of time per unit of time with a given factor services ratio. In what follows, m will be referred to as the *utilization ratio*.

The rate of depreciation δ is by (8) a positive strictly convex function of m; positivity of δ is a natural assumption to make, whereas convexity is assumed for the sake of analytical convenience; the condition $\lim_{m\to 1} g(m)=\infty$ is innocuous and it will be used to guarantee that efficient m's are less than unity; however, there may be some justification for it if we interpret $m=1$ as the case where machines are operated at a maximum speed or without stopping for repairs (recall interpretations (a) and (b) above).

II. Efficient and Competitive Utilization Ratios

By (3) and (5) we can assure that it is efficient[2] to employ all the available labor services;[3] thus $N_t=L_t$ for every t.

Let us define

$k_t = \frac{K_t}{L_t}$ = ratio of available capital services to available labor services at time t

$$y_t = \frac{Y_t}{L_t}, \qquad c_t = \frac{C_t}{L_t}$$

So we can write, recalling (3),

$$y_t = f(m_t k_t) \tag{9}$$

where $f(x) = F(x, 1)$

Moreover, by (3),[4]

(10)(a) $f(x)$ is continuous for all $x \geq 0$

(b) $f(0) = 0$

(c) $f'(x) > 0$

(d) $f''(x) < 0$ for all $x > 0$

---

[2] As usual we call efficient any feasible per capita consumption path such that there is no other feasible per capita path yielding larger consumption (for a non-null set of points of the real line).

[3] Notice that this would not necessarily be the case if isoquants were L-shaped.

[4] Tjalling Koopmans, p. 236, has shown that if equations (3a–g) hold, there is some $\hat{x}$ such that $f(x) \leq nx$ for all $x \geq \hat{x}$. The latter together with (10c and d) readily implies (10f).

(e) $$\lim_{x\to 0} f'(x) = \infty$$

(f) $$\lim_{x\to 0} [f(x) - nx] = -\infty$$

Due to the fact that we are in an essentially one-good economy, static efficiency suffices to determine the value of m_t. Clearly, we will choose m so as to

$$\max_{1\geq m\geq 0} [f(mk_t) - g(m)k_t] \tag{11}$$

By (8) and (10) there exists a unique interior solution. It satisfies the following first-order necessary condition when $k_t > 0$,

$$f'(mk_t) = g'(m) \tag{12}$$

In other words, efficient utilization of capital at a given point in time t calls for equating the marginal productivity, $f'(mk_t)$, to the marginal cost of capital services at t, $g'(m)$. Figure 1 shows how the efficient level of m—indicated by $m^*(k_t)$—is determined. Notice that since $f'' < 0$, f' will shift to the left in Figure 1 as k_t is increased; hence,

$$\frac{dm^*(k)}{dk} < 0 \tag{13}$$

Thus, the efficient utilization ratio decreases as the ratio of the available capital to labor services k is increased. To put it differently, the richer is this idealized economy in terms of available capital services per capita, the smaller will be the (efficient) share of total available capital services utilized.

By (8) and (12) it readily follows

$$\lim_{k\to 0} m^*(k) = 1 \tag{14}$$

On the other hand, in a competitive situation the (instantaneous) real rate of interest r should in equilibrium be equal to the net marginal productivity of the capital stock, i.e.,

$$f'(m_t k_t)m_t - g(m_t) = r_t \tag{15}$$

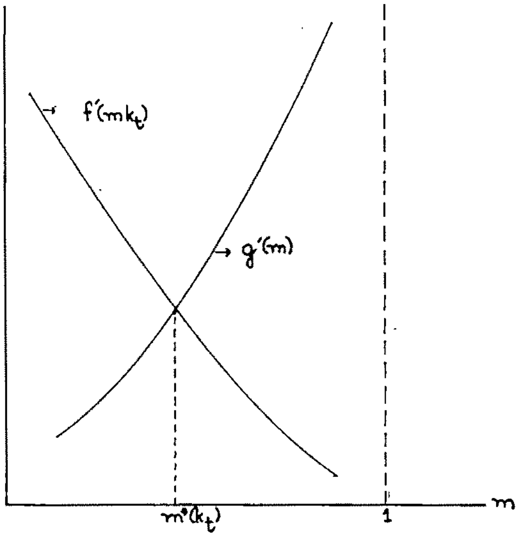

FIGURE 1

Moreover, it is clear that profit maximization implies $m_t = m^*(k)$. Hence, by (12) and (14), we get

$$g'(m_t)m_t - g(m_t) = r_t \tag{16}$$

By implicit differentiation of (16) we obtain

$$\frac{dm_t}{dr_t} = \frac{1}{g''(m_t)m_t} > 0 \tag{17}$$

i.e., the larger is the rate of interest the larger will also be the utilization ratio.

An interesting implication of our assumptions is that by (16), the utilization ratio can be determined as soon as r_t is known, and that calculations can be performed by using function g exclusively.

Finally, differentiating (12) totally with respect to k yields

$$f''(mk)\frac{d(mk)}{dk} = g''(m)\frac{dm^*(k)}{dk} \tag{18}$$

and since $dm^*(k)/dk < 0$, we get

$$\frac{d(mk)}{dk} > 0 \tag{19}$$

which means that the ratio of capital services *used* to the labor services *used*, mk, is positively correlated to the corresponding ratio of *available* factor services k. Notice that this is obtained despite the fact that the efficient utilization ratio $m^*(k)$ is negatively correlated with k (recall (13)).

III. Optimal Utilization Ratios

In view of (1)–(7), the notation introduced in Section II, and assuming efficiency, one can write without loss of generality,

$$(20)\quad \begin{aligned} Dk_t &= f(m_t k_t) - [g(m_t) + n]k_t - c_t \\ &= h(k_t) - c_t \end{aligned}$$

where

$$(21)\quad h(k) \equiv f(m^*(k)k) - [g(m^*(k)) + n]k$$

Clearly, $f(k) - nk \geq f(mk) - [\delta + n]k$, and hence, by (10f),

$$(22)\qquad \lim_{k\to\infty} h(k) = -\infty$$

On the other hand, recalling (12), for all $0<k$ we have

$$(23)\quad \begin{aligned} h'(k) &= f'(m^*(k)k)[m^{*\prime}(k)k + m^*(k)] \\ &\quad - g'(m^*(k))m^{*\prime}(k)k - g(m^*(k)) - n \\ &= f'(m^*(k)k)m^*(k) - g(m^*(k)) - n \\ &= g'(m^*(k))m^*(k) - g(m^*(k)) - n \end{aligned}$$

hence, by (13) and (23), for all $k>0$,

$$(24)\quad h''(k) = g''(m^*(k))m^*(k)m^{*\prime}(k) < 0$$

For any given $0 \leq m < 1$, (10) can be used to show that there is some $\bar{k} > 0$ such that for all $0 < k < \bar{k}$

$$(25)\quad f(mk) - [g(m) + n]k > 0$$

while

$$(26)\quad f(mk) - [g(m) + n]k = 0 \quad \text{for } k = 0$$

Hence, since $m^*(k)$ solves (11), then (22), (24), and (25) imply the existence of some $\bar{k} > 0$ such that

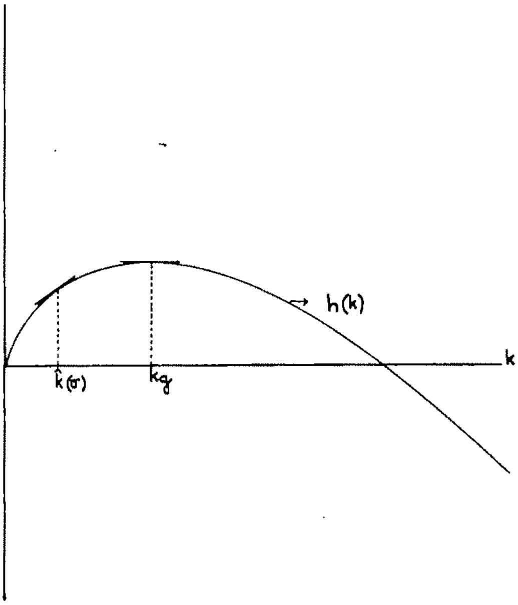

FIGURE 2

$$(27)\quad h(k) > 0 \quad \text{if and only if} \quad 0 < k < \bar{k}$$

Furthermore, by (8b) and (26),

$$(28)\qquad h(0) = 0$$

Figure 2 depicts a function satisfying (24), (27), and (28).

We are now ready to prove the first central result of this section.

PROPOSITION 1: *There exists one and only one golden rule capital-labor ratio, k_g. The corresponding unique golden rule utilization ratio m_g satisfies*

$$(29)\qquad g'(m)m - g(m) = n$$

PROOF:

From (20), golden rule consumption per capita c_g satisfies

$$(30)\qquad c_g = \max_{k\geq 0} h(k) = h(k_g)$$

By (24), (27), and (28), k exists and is unique. Also $h(k_g) > 0$ (see Figure 2). Clearly, by (23) and (30),

$$0 = h'(k_0) = g'(m^*(k_0))m^*(k_0) - g(m^*(k_0)) - n \tag{31}$$

By (8), $g'(m)m-g(m)$ is a strictly increasing function of m, $0 \leq m < 1$; hence, there is a unique m for which (31) holds. Existence of m_g follows from the fact that $m_g = m^*(k_g)$ for which existence has been proved above.

Remark: Equation (16) above and Proposition 1 imply that, as usual, the (instantaneous) real rate of interest in the golden rule path equals the rate of growth of labor. In fact, given the latter and the depreciation function, one can use (16) to determine m_g. The golden rule value of the utilization ratio becomes, under the present assumptions, completely independent of the production function.

The present model can easily be suited to study optimal utilization ratios in an optimal growth plan. Consider the following problem:

$$\max \int_0^\infty u(c_t)e^{-\sigma t}dt \qquad \sigma > 0 \tag{32}$$

subject to $Dk_t = h(k_t) - c_t$

$$k_t \geq 0, \quad c_t \geq 0 \qquad \text{for every t}$$

$$k_0 \text{ given}$$

where u is assumed to be strictly concave and increasing, and to satisfy $\lim_{c \to 0} u(c) = -\infty$. Functions associated with the solution of (32) will be called optimal. Let us define $\hat{k}(\sigma)$ as the value of k such that (see Figure 2)

$$h'(\hat{k}) = \sigma \tag{33}$$

$\hat{k}(\sigma)$ exists and it is unique. Existence is shown in the Appendix; uniqueness, on the other hand, follows from (24).

PROPOSITION 2: *For any initial capital-labor ratio* $\bar{k} > k_0 > 0$,[5] *there exists a unique optimal path of* k*'s;* k_t *converges monotonically to* $\hat{k}(\sigma)$. *The associated* $m_t = m^*(k_t)$ *converges monotonically to* $m^*(\hat{k}(\sigma))$.

PROOF:

Existence and monotonic convergence of k will not be proved here since it involves a trivial application of results obtained by Koopmans, for example.

Monotonicity and convergence of m_t follows directly from the properties of the optimal path of k's and (13).

Remark: Since by (13) there is an inverse relationship between m and k, we have that if in an optimal plan $k_0 < \hat{k}(\sigma)$ $[k_0 > \hat{k}(\sigma)]$, then $m_0 > m^*(\hat{k}(\sigma))$ $[m_0 < m^*(\hat{k}(\sigma))]$; therefore optimal k_t increases (decreases) and optimal m_t decreases (increases) over time. By (23) and (33) we have

$$\sigma = h'(\hat{k}(\sigma)) = g'(m^*(\hat{k}(\sigma))m^*(\hat{k}(\sigma)) - g(m^*(\hat{k}(\sigma))) - n \tag{34}$$

But, by a similar argument as in the previous Remark, one can show that there is one and only one m for which (34) holds true. The asymptotic value of m is again wholly independent of the production function.

In view of (16) and the results of this section it would be interesting to find out about the family of functions $z(m)$ satisfying (8) such that

$$z'(m)m - z(m) = g'(m)m - g(m) \qquad \text{for every } 0 \leq m < 1 \tag{35}$$

It can easily be shown that every function belonging to that family can be expressed as

$$z(m) = g(m) + bm, \quad \text{for some } b \text{ such that } -bm \leq g(m), \qquad \text{for all } 0 \leq m < 1 \tag{36}$$

Therefore, golden rule and optimal utilization ratios are not going to be affected by changing the depreciation function from g to z (satisfying (8)) as long as $z'(m)$

---

[5] Recall the definition of $\bar{k}$ in (27).

$-g'(m)=b=$ constant for all $0\leq m<1$, and $z(0)=g(0)$.

APPENDIX

LEMMA: *Let* $\sigma>0$; *then there is some* $k>0$ *such that* $h'(k)=\sigma$.

PROOF:

Taking into account (22), (24), and (27), it is sufficient to show

$$\text{(A1)} \qquad \lim_{k\to 0} h'(k) = \infty$$

By (14) and (23), the latter is equivalent to

$$\text{(A2)} \qquad \lim_{m\to 1} [g'(m)m - g(m)] = \infty$$

We will show that (A2) holds given that g satisfies (8). First notice that

$$\text{(A3)} \qquad \frac{d}{dm}[g'(m)m - g(m)] = g''(m)m > 0$$

Suppose now that (A2) is false. Then by (A3),

$$\text{(A4)} \qquad \lim_{m\to 1} [g'(m)m - g(m)] = B, \qquad B \text{ a real number}$$

Moreover, by (A3)

$$\text{(A5)} \qquad B > -g(0)$$

Due to (8c and d) there is some $\bar{m}<1$ such that

$$\text{(A6)(a)} \qquad g(\bar{m}) > 0$$

$$\text{(b)} \quad g(m) \text{ is increasing for all } 1 \geq m \geq \bar{m}$$

Thus (A4) is equivalent to

$$\text{(A7)} \qquad \lim_{m\to 1} \left[\frac{g'(m)m}{g(m)} - 1\right] g(m) = B$$

The latter implies, recalling (8d), (A5), and (A6),

$$\text{(A8)} \qquad \lim_{m\to 1} \frac{g'(m)}{g(m)} = 1$$

or equivalently,

$$\text{(A8')} \qquad \lim_{m\to 1} \frac{d\, ln\, g(m)}{dm} = 1$$

Hence, for every $\epsilon>0$, there is some $0<\hat{m}(\epsilon)<1$, such that

$$\text{(A9)} \qquad \frac{d\, ln\, g(m)}{dm} < 1 + \epsilon, \qquad \text{for all } 1 \geq m > \hat{m}(\epsilon)$$

Therefore,

$$\text{(A10)} \qquad ln\, g(m) < ln\, g(\hat{m}(\epsilon)) + (1+\epsilon)(m - \hat{m}(\epsilon)) \qquad \text{for all } 1 \geq m > \hat{m}(\epsilon)$$

which is equivalent to

$$\text{(A11)} \qquad g(m) < g(\hat{m}(\epsilon)) \exp\left[(1+\epsilon)(m-\hat{m}(\epsilon))\right] \qquad \text{for all } 1 \geq m > \hat{m}(\epsilon)$$

Hence,

$$\text{(A12)} \qquad g(1) < g(\hat{m}(\epsilon)) \exp\left[(1+\epsilon)(1-\hat{m}(\epsilon))\right] < \infty$$

contradicting (8d). Therefore (A2) holds and the Lemma follows.

International Trade and Economic Growth: A Diagrammatic Analysis

By ROBERT E. BALDWIN*

As others have noted (see articles by Harry Johnson (1971, 1972) and Jaroslav Vanek), the highly mathematical nature of most of the literature integrating growth and trade theory serves to restrict considerably the size of the audience to which explanations of this important subject can be directed.[1] This paper attempts to widen this audience by framing the analysis of the topic in simple geometric terms that utilize the standard two-country, two-sector (commodity), two-factor model of international trade.

Assume that the two commodities produced by the two countries A and B are a capital good K and a consumption good C. The capital good together with a growing labor force L are the two factors of production.[2] As is typical for this model, also suppose that the capital good cannot be traded once it is used as a productive factor and that this good is produced in a uniformly labor-intensive fashion compared to the consumption good.[3] The production function of each good is identical in both countries and subject to constant returns to scale.[4] It is further assumed that the growth rate of the labor force is the same in both countries and that each economy saves a constant but different proportion of its income.[5]

There are two requirements for steady-state equilibrium in such a model: 1) The desired rate of capital accumulation in both countries must equal the exogenously determined rate of growth of the labor force, and 2) The value of exports must equal the value of imports for each of the two countries.[6] As the first step in the analysis, it will be shown that over some range of capital-labor (K/L) endowment ratios for each country, there is for each of these endowment ratios some relative price of the capital good in terms of the consumption good (P_k) that will equalize the desired rate of capital accumulation in each country and the common rate of labor force growth. After finding the set of P_k and K/L ratios for each country satisfying this equilibrium condition, the next step will be to select the subset of P_k at which the two countries wish to trade in opposite directions, and determine for each of these P_k the relative size of the countries as measured by the ratio of their labor supplies that would be needed to equalize the value of exports and imports in each country. Given some actual initial ratio of the size of the two labor forces—a ratio that remains constant throughout the growth process, since the rates of labor force growth are equal in the two countries—it will then be possible to read off from this schedule of

---

* Professor of economics, University of Wisconsin, Madison.

[1] The exposition of these authors deals mainly with the case of a small country facing fixed terms of trade whereas the analysis here focuses on the more general case where there are two countries, each of which can affect the terms of trade.

[2] For simplicity, depreciation of the capital good is ignored. Some initial supply of K and L in each country is also assumed.

[3] This assumption concerning factor intensity is made to insure a unique, stable steady-state equilibrium.

[4] Such other standard assumptions of the simple Heckscher-Ohlin-Samuelson model as diminishing marginal productivity and perfect competition are also made.

[5] In each economy, all individuals have the same savings ratio and possess the same quantity of capital.

[6] When the *desired* rate of capital accumulation in a country equals the labor force growth rate, the country's supply of the capital good will generally not equal its demand for this good. However, the trading condition required for equilibrium insures that one country's excess demand for K is matched by the other country's excess supply. Thus, the two requirements can be combined into the more familiar condition that the *actual* rate of capital accumulation equal the common growth rate of the labor force.

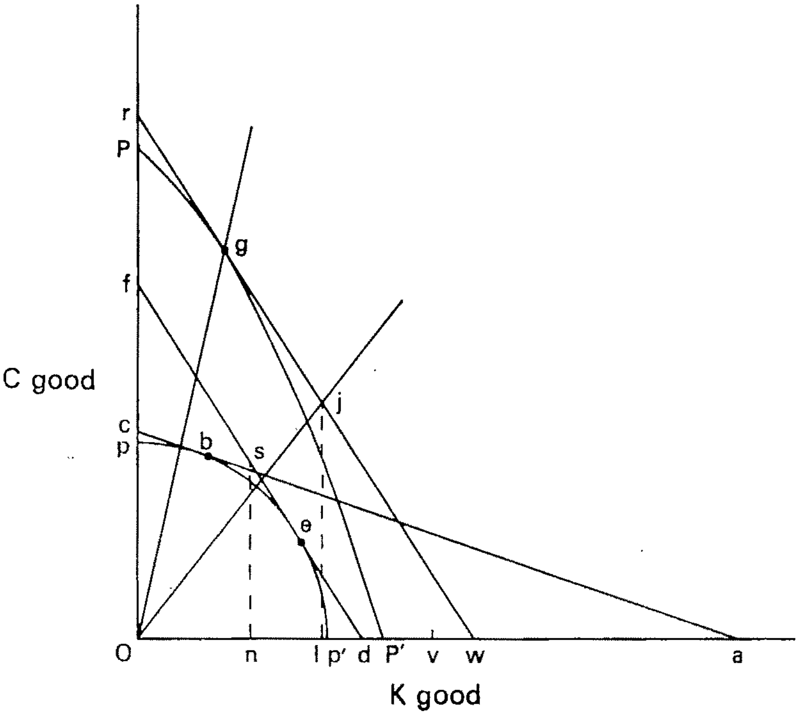

FIGURE 1

hypothetical relative sizes of the two countries that equalize trade at different P_k, the particular P_k and related L/K ratios that satisfy both equilibrium conditions.

I. Determining Possible Equilibrium Capital-Labor Ratios

To begin with the first step, the manner in which the desired rate of accumulation varies with changes in the relative price of the capital good is depicted in Figure 1. The curve pp' represents country A's per worker production possibilities for the two goods given a particular stock of capital per member of the labor force. At the relative price of the capital good indicated by the slope of the line abc, the value of output per worker measured in terms of the capital good would be Oa. If the saving ratio is $\frac{1}{2}$, the amount of capital per worker that the economy would desire to add to its capital stock would be Ov, i.e., $\frac{1}{2}$ of Oa. On the other hand, if P_k rises to the slope indicated by def, desired investment would decline to On, i.e., $\frac{1}{2}$ of Od. Thus, given a particular K/L endowment ratio, the lower the price of the capital good, the higher will be the desired rate of capital accumulation.[7]

This relationship between P_k and the rate of capital accumulation, given a fixed K/L endowment ratio, for example, K_1/L_1, is depicted in Figure 2. As can be seen from a consideration of Figure 1, for all prices of the capital good at which the country is completely specialized on this commodity, the rate of capital accumulation becomes fixed. The P_k, accumulation-rate curve, K_1/L_1, in Figure 2 thus becomes vertical. On the other hand, the rate of accumulation continues to rise as P_k falls below the price at which complete specialization on the consumption good occurs, i.e., below the price at which the curve cc' intersects the P_k, accumulation-rate curve, K_1/L_1.

Relating P_k and the rate of capital ac-

---

[7] The desired accumulation rate per worker is, of course, also the desired accumulation rate for the economy as a whole.

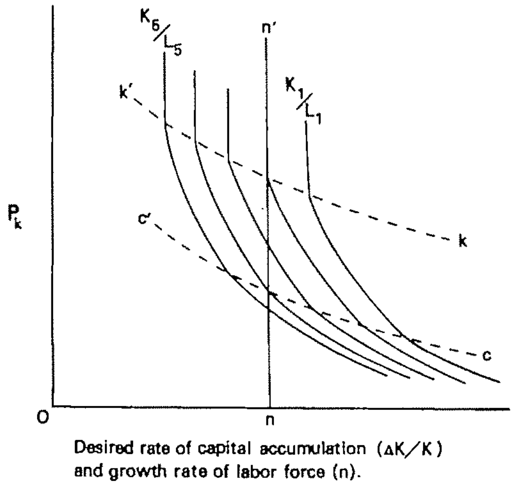

FIGURE 2

cumulation for a K/L ratio higher than K_1/L_1 results in a shift in the P_k, accumulation-rate curve to the left. This can be seen in the following way. Suppose the total capital endowment available to a given number of workers who produce both the capital and consumption good is increased, while the relative prices of the two goods remain fixed. As is well known from the analysis of this problem in terms of the Bowley-Edgeworth box diagram, the output of the two goods will be adjusted so that the marginal productivities of capital and labor remain unchanged. This means that the income accruing to capital increases in the same proportion as the increase in the capital stock, whereas the income earned by the fixed labor supply remains unchanged. The sum of the income earned by capital and labor, therefore, increases a smaller percentage than the increase in the capital stock. The volume of desired savings and investment, which is proportional to the level of total income, will consequently not rise as much relatively as the increase in K/L (which equals the proportionate increase in the capital stock), and the rate of accumulation will decline at any P_k.[8] As depicted by the curves kk' and cc' in Figure 2, the capital-good prices at which specialization on the capital good (shown by kk') and on the consumption good (shown by cc') occur, increase as K/L rises. This follows from the nature of the Rybczynski effect

---

[8] If only one good is produced before and after the increase in K, the fact that total income rises relatively less than the relative increase in K follows directly from the assumption that the production functions exhibit diminishing marginal productivity.

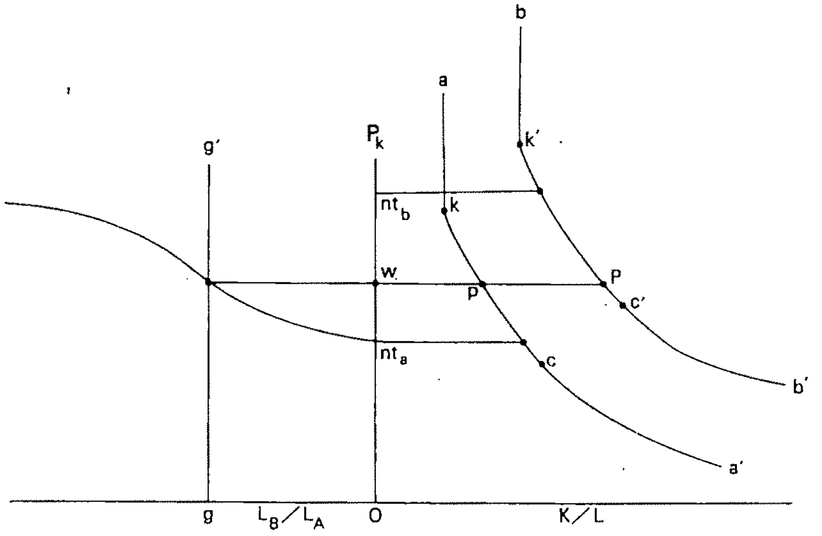

FIGURE 3

when the capital good is labor intensive compared to the consumption good.[9]

The distance *On* in Figure 2 indicates the given rate of labor force growth. Therefore, by drawing a vertical line *nn'* at *On*, it is possible to read off all the P_k and K/L ratios which satisfy the condition that the desired rate of capital accumulation equal the rate of labor force growth. The curve *aa'* in Figure 3 depicts the set of such points for country *A*. Since the savings ratio in country *B* is assumed to be greater than in *A*, the curves in Figure 2 relating P_k to the rates of capital accumulation for various K/L ratios are further to the right for country *B* than for country *A*. This in turn implies that for country *B*, the set of points indicating all possible P_k and K/L ratios satisfying the equilibrium condition that the desired rate of capital accumulation equal the rate of labor force growth behaves like the curve *bb'* in Figure 3. The points where each curve becomes vertical (*k* and *k'*) indicate the P_k and K/L ratios at which specialization on the capital good occurs, while *c* and *c'* depict where specialization on the consumption good takes place for the two countries.

II. Introducing the Market-Clearing Condition

As previously mentioned, besides the equilibrium requirement that the desired accumulation rate in each country equal the common labor force growth rate, the excess domestic demand of one country for a particular commodity must equal the excess domestic supply of that commodity by the other country. Over some range of the P_k and K/L ratios that satisfy the first equilibrium condition, the two countries will wish to trade in opposite directions, i.e., a commodity that one country wishes to export the other country wishes to import. For each of these P_k there is some hypothetical relative size of the two countries, as measured by the ratio of their labor (or capital) supplies, that will satisfy the equilibrium requirement relating to trade.

Consider, for example, the P_k level *Ow* in Figure 3 and the corresponding K/L ratios, *wp* and *wP* for countries *A* and *B*, respectively. Suppose that the curves *pp'* and *PP'* in Figure 1 represent the per worker production-possibility curves of countries *A* and *B*, respectively, that are associated with these K/L ratios. Furthermore, let the capital-good price *Ow* be indicated in this figure by the common slope of the lines *def* and *wgr*. With this price ratio, country *A*'s per worker production point will be *e* and—assuming a savings ratio of $\frac{1}{2}$—each individual will wish to trade by exporting the capital good and importing the consumption good until the point *s* is reached, since $\frac{1}{2}$ of *Od* equals *On*. In country *B*, where the per worker savings ratio is assumed to be greater than $\frac{1}{2}$, the per worker production point will be at *g*, and each individual will desire to trade along the budget line *wgr* until the point *j* is reached (*Ol* is more than $\frac{1}{2}$ of *Ow*). Since the trading distance *gj* is longer (actually twice as long) than *es*, the two countries cannot be of equal size in terms of their labor endowments and still achieve a trading equilibrium at the given P_k. However, since at the given P_k each worker in country *A* wishes to export only one-half the volume of *K* that each worker in country *B* wishes to import, if there are twice as many workers in country *A* as in country *B* (each with the capital endowment of the country *A* worker whose production-possibility curve is depicted in Figure 1), country *A*'s total exports of *K* would equal the total volume of country *B*'s imports of this good. This ratio of the size of the labor force in country *B* (L_B) to the size in country *A* (L_A)—$L_B/L_A = \frac{1}{2}$ in this case—that is needed to equate exports and imports at the given P_k and K/L ratios is plotted in the left quadrant of Figure 3 at the given P_k.

Next select a lower P_k than *Ow* and consider the magnitude of the L_B/L_A ratio required for trading equilibrium at this lower P_k and its associated K/L ratios in the two countries. The right side of Figure 3 indicates that the growth-equilibrium K/L

---

[9] Increasing the volume of capital per worker shifts the per worker production-possibility curve outward in such a manner that the slope of the curve increases at its intersection points with both the capital-good and the consumption-good axes.

ratios for the two countries are larger than at the P_k ratio of Ow. It is convenient to think of the change in P_k and K/L ratios as taking place in two steps: first, by an increase in the K/L ratios with P_k remaining constant, and then by a decrease in P_k with the K/L ratios being held at their higher levels. Both of these changes act in both countries to increase per worker demand for the capital good and decrease per worker supply. For example, referring again to Figure 1, suppose that the ratio of capital per worker is increased from the ratio that gives the per worker production-possibility curve pp', while P_k is held constant at the level indicated by the slope of def. From the Rybczynski theorem we know that if the capital good is labor intensive, the per worker production-possibility curve will shift to positions such as PP', where at the previous P_k (equals the slope of wgr) the output of the capital good declines as compared to its previous level. Since income per worker measured in terms of the capital good and at the fixed P_k increases (from Od to Ow), the demand for the capital good increases. Similarly, if the price of the capital good in terms of the consumption good is decreased while the K/L ratio is kept fixed at its new higher level, production of the capital good declines further and income, and thus investment demand, increases still more.

Since country A exports the capital good in return for the consumption commodity whereas country B does the opposite, the effect of lowering P_k and increasing the K/L ratio in both countries will be to reduce A's per worker excess supply of the capital good and increase B's per worker excess demand for this good. Therefore, for the relative size of the two countries that produced trading equilibrium with the previous higher P_k, the demand for the capital good on the part of country B will exceed the supply from country A. To achieve trading equilibrium at the lower P_k and higher K/L ratios, it is necessary to decrease the size of country B relative to country A, i.e., reduce L_B/L_A. This will have the effect of bringing about trading equilibrium by increasing the supply of the capital good relative to the demand for this commodity. It follows, therefore, that the shape of the P_k, L_B/L_A equilibrium curve in Figure 3 will be such that as P_k decreases, L_B/L_A also decreases.

The P_k, L_B/L_A curve will range between the two P_k ratios that define the points where both countries will wish to export (or import) the same commodity, i.e., the curves will range between the no-trade points of the two countries. For country A, as P_k continues to decrease below Ow and the per worker K/L ratio increases beyond wp, excess supply will finally decline to zero at a point such as Ont_a, and the associated K/L ratio will be country A's steady-state equilibrium position in the absence of international trade. Since country B's K/L ratio at this P_k as well as its savings propensity is higher than A's, B will be a net demander of the capital good at the P_k that represents A's no-trade equilibrium. At P_k ratios below Ont_a, country B's excess demand for the capital good will be even greater, whereas country A will also wish to import the capital good. To find country B's no-trade equilibrium, P_k must be increased and the K/L ratio decreased. These changes will decrease per worker demand for the capital good and increase its supply. Thus, a P_k such as Ont_b will be where country B ceases to be a net demander of the capital good.[10]

---

[10] Unlike the situation depicted in Figure 3, the autarchy points Ont_a and Ont_b could lie in the P_k range where both countries produced both commodities. The equilibrium K/L ratio for country B at its no-trade equilibrium point must, however, be greater than the K/L ratio at A's no-trade equilibrium point. Consider, for example, whether the two equilibrium K/L ratios could be the same. With the same K/L ratio the total demand for K would be the same in both countries, since the rate of accumulation is the same at all points on both P_k, K/L curves. However, since the no-trade P_k for country B must be higher than for A, country B's production of K would be greater than for country A with the same K/L ratio. Thus if excess demand and supply were zero for country A, i.e., if it were at its no-trade equilibrium point, excess supply would have to be positive in country B. With a P_k higher than prevails in country A, lowering the K/L ratio for country B merely increases its excess supply. Thus a higher K/L is necessary in country B than in A in order to decrease its production of K and increase its demand for K at a given P_k and reduce excess supply to zero.

At points above Ont_b, both A and B will wish to export the capital good.

Consider the shape of the P_k, L_B/L_A curve as it approaches the two no-trade P_k ratios. As the P_k ratio Ont_b is approached from below, country A's per worker excess supply of the capital good increases and country B's per worker excess demand for this good decreases. However, by increasing the size of country B relative to country A, it will always be possible to make B's excess demand for the capital good sufficiently large to equal the excess supply of this good from A. The closer the capital-good price is to Ont_b, the higher the L_B/L_A ratio must become in order to make demand equal supply. Therefore, the equilibrium L_B/L_A ratio approaches infinity as Ont_b is approached. When Ont_b is reached, country A's excess supply of the capital good is negligible compared to B's consumption of this good, and country A in effect faces an infinitely elastic demand curve for the capital good. Conversely, at the P_k ratio Ont_a, country B is negligible in size compared to country A and in effect faces an infinitely elastic supply curve of the capital good.

III. Equilibrium Possibilities

The last step in determining the steady-state equilibrium P_k and K/L ratios for the two countries is to mark the actual initial ratio of the labor supplies in the two countries on the L_B/L_A axis in Figure 3. Since the labor supplies grow at the same rate in both countries, this ratio never changes for the two countries. If this ratio is Og, the P_k and the K/L ratio that satisfies both the trade and accumulation equilibrium conditions for steady-state growth are Ow for the capital-good price and wp and wP for the capital-labor ratios for countries A and B, respectively. Both of the countries are incompletely specialized when Og is the ratio of labor supplies in the two countries.[11] However, if initial relative labor supplies are such that the equilibrium P_k ratio is only slightly above Ont_a, country A will produce both goods but country B will be completely specialized on the consumption good. On the other hand, if the L_B/L_A ratio is sufficiently high to give an equilibrium P_k level only slightly below Ont_b, country A will become completely specialized on the capital good whereas country B will produce both goods. There are four additional possible patterns of specialization.[12] If the savings ratios for the two countries are simply reversed, then country B's P_k, K/L curve will lie to the left of country A's.[13] This makes it possible for country A to specialize in the production of the consumption good while country B produces both goods (exporting the capital good) and also for country B to specialize in the production of the capital good whereas country A produces both commodities. The last two possible cases arise if the savings ratios of the two countries differ so much that the P_k level at the point where one of the countries becomes completely specialized on the consumption good is higher than the P_k level at which complete specialization on the capital good by the other country begins. If country B has the higher savings ratio, this country will specialize on the consumption good, while country A will specialize on the capital good. Reversing the the positions of the two countries in these circumstances gives the other possible specialization case.

In all of these seven possibilities the country with the smaller savings ratio (and thus with the P_k, K/L curve further to the left in Figure 3) will have a lower P_k prior to trade and thus will increase is production of the capital good after trade is opened up and export this commodity. In a sense, the country with the lower savings ratio has a demand-induced comparative advantage in the labor-intensive good relative to the capital-intensive commodity.[14] The other country increases the production of the consumption good and exports this good. Since the capital good is labor intensive compared to the consumption good, these shifts in production—in accordance with the Stolper-Samuelson theorem—increase the wage rate and decrease the rental return to capital in the capital-exporting country as compared with its no-trade position. Factor returns in the other country move in the opposite direction as trade is opened up.

---

[11] Since both countries are incompletely specialized, the capital-labor ratio employed in producing each good will be the same in both countries, and the wage-rental ratio will be identical for the two countries.

[12] See Murray Kemp, pp. 222–24.

[13] Since the x-axis in the left-hand part of Figure 3 is the ratio of the labor supply in the country with the higher savings propensity to the labor supply in the country with the lower savings propensity, consistency requires this axis to be labelled the ratio of L_A to L_B.

Consider P_k somewhat above and below the point where the P_k, L_B/L_A curve intersects the vertical line gg', which indicates the actual L_B/L_A ratio for the two countries. Since at P_k above this intersection point the actual L_B/L_A ratio is less than the L_B/L_A ratio that would fulfill the trading equilibrium condition, country B's excess demand for the capital good will be less than country A's excess supply. The price of the capital good would therefore tend to decline and the K/L ratios in both countries to rise in response to the fall in the price of the capital good. By similar reasoning, P_k ratios which are below the equilibrium level result in country B's excess demand for the capital good being greater than country A's excess supply. This relationship in turn tends to increase the price of the capital good and reduce the K/L ratios in the two countries. Hiroshi Atsumi has shown that when the trading-equilibrium position for the commodity offers associated with all the possible steady-state P_k, K/L ratios (as shown by the aa' and bb' curves in Figure 3) is stable, the growth paths of the two countries will converge to the equilibrium L_B/L_A, P_k, and K/L ratios indicated at the intersection point of the P_k, L_B/L_A curve and the gg' line.

The effects of such parametric changes as an increase in one country's savings ratio, an increase in the common rate of labor force growth (or even the introduction of unequal rates of labor force growth), and the imposition by one of the countries of a tariff on either the capital or consumption good can easily be analyzed with the aid of Figures 2 and 3. By causing the P_k, K/L curves in Figure 3 to shift, these changes lead to shifts in the P_k, L_B/L_A curve in that diagram and thus to new equilibria for P_k and the K/L ratios.

[14] If the savings ratios are the same in both countries, the steady-state position will be characterized by identical K/L ratios for the two countries, and no trade. In terms of Figure 3 there would be only one P_k, K/L curve in the right-hand quadrant and the P_L, L_B/L_A curve on the left-hand side would be a horizontal line at the P_k level indicating the no-trade position on the P_k, K/L curve.

Lancaster's New Approach to Consumer Demand and Its Limitations

By REUVEN HENDLER[*]

Recently, Kelvin Lancaster (1971) has presented an extension of his earlier approach to the theory of consumer demand (1966a, b). Lancaster's "new approach to consumer theory" is presented as a more general theory of consumer behavior than the traditional one, and is supposed to be "a model very many times richer in heuristic explanatory and predictive power than the conventional model of consumer behavior" (1966a, pp. 154–55). The major contribution of the new approach is dependent on the ability to distinguish between objective and subjective choice and demand theory. However, it is the purpose of this paper to show that this new approach is relevant only under restrictive assumptions in regard to either the nature of the goods consumed or the consumer's utility function.

I

Originally, Lancaster introduced the idea that goods are consumed for the characteristics they possess and they are the objects of consumer preference or utility, with the number of characteristics being greater, equal, or smaller than the number of goods available to the consumer. It is assumed that the characteristics possessed by a good or a combination of goods are, in principle at least, objective and the same for all consumers. The utility derived by the consumer, on the other hand, is subjective and depends on his preference function. Briefly, given the units of measurement any good contains the same amount of any characteristic for all consumers, but each consumer may derive a different level of utility from consuming those characteristics. (See Lancaster (1971, p. 7) and (1966a, p. 134.)

The Lancaster model can be illustrated by considering a simplified choice set of two characteristics A and B, and three goods X, Y, and Z. "Each good gives rise to a vector of the two characteristics, and the consumption technology consists of the activities, consuming each of the goods separately, and consuming them in linear combination" (1966b, p. 16). The imposition of the budgetary constraint on the goods yields the characteristic vectors which confront the consumer. Figure 1 illustrates a case where given the income-price situation, the consumer may obtain points c, d, or e by spending his total income on X, Y, or Z, respectively. The points inside and on the triangle cde represent the bundles of characteristics which are attainable by linear combinations of X, Y, and Z. Lancaster has argued that an efficient consumer will choose combinations on ced, the consumer efficiency frontier. The efficiency frontier changes with relative prices. As the price of Z increases, the characteristics vector which the consumer may obtain

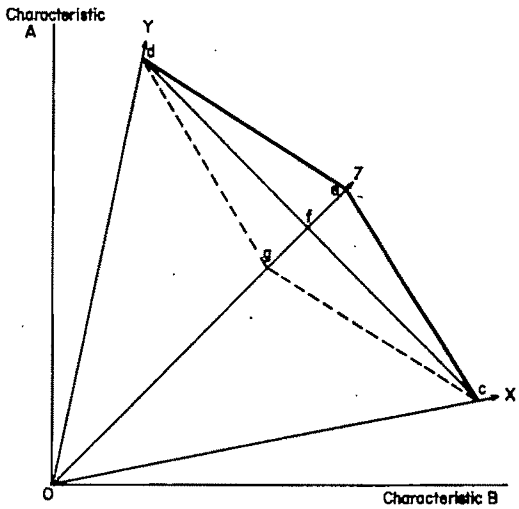

FIGURE 1

---

[*] Senior economist, Gruen, Gruen and Associates; originally written while assistant professor of economics at Temple University. I would like to thank Robert H. Deans for his valuable comments.

by spending all of his income on Z will move toward the origin. If the price of Z increases so that a point left of cd (say, g) becomes the new vector, no combination using Z would be used and cd would become the efficiency frontier, independent of the individual's utility function. Individual preference will determine consumer's equilibrium point on the objective efficiency frontier. The existence of the objective frontier makes it possible to distinguish between two separate effects of any change in income or relative prices: 1) the efficiency substitution effect resulting from a shift in the efficiency frontier, which is objective and independent of the individual consumer's preference function, and 2) the personal substitution effect which depends on the individual's preference function and is similar to the traditional substitution effect. (See Lancaster (1971, pp. 53–65) and (1966a, p. 143).) The existence of the efficiency substitution effect enables the objective observer to make a judgment in respect to the consumer's behavior, even without any knowledge about the latter's utility function.

Such an approach would enable economists to determine, for example, the maximum price above which there should be no demand by efficient consumers.[1] The crucial question is whether the model's assumptions are at least as general as those made by traditional consumer theory, for if the assumptions of the Lancaster model are found to be more restrictive than those of the traditional approach, then it becomes only a special case rather than a general theory of demand. Since the objective efficiency frontier is the foundation of the Lancaster model, it is necessary to examine some of the assumptions required for deriving the efficiency frontier, the meaning and validity of which Lancaster did not analyze.

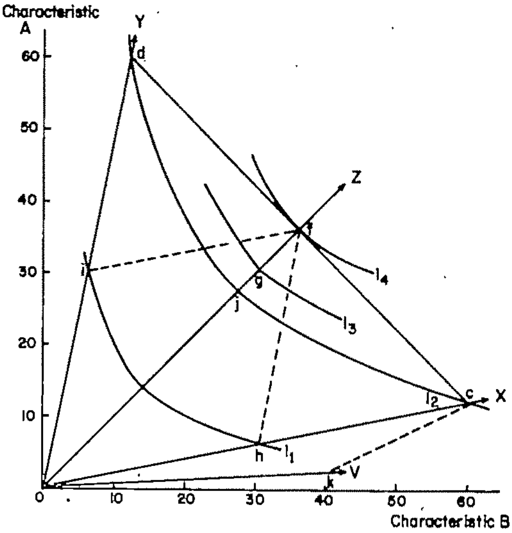

FIGURE 2

II

By considering a choice set of two characteristics A and B and four goods V, X, Y, and Z, and imposing a budget constraint, the characteristic vectors k, c, g, and d in Figure 2 can be derived. According to Lancaster, the efficiency frontier would be cd (i.e., regardless of his preference function the informed consumer should never purchase goods V and Z with the given budget constraint, for by consuming combinations of X and Y the consumer obtains larger quantities of both characteristics than by consuming goods V or Z).[2] Point c, for example, is objectively more efficient than point k. The validity of this argument rests on the assumption that the marginal utility of characteristics may never be negative. Such an assumption of nonnegativity of marginal utility (NNU) is a very restrictive assumption which transcends the assumption that the marginal utility of a good is always positive.[3] While the marginal utility of a good may be high (or even increasing), some of its characteristics may convey disutility. An individual may enjoy eating a sandwich because of its flavor and texture characteristics while experiencing disutility from other characteristics which the sandwich contains, such as its bulk or calorie content. Another individual (or the same person at another time) may feel hungry and therefore enjoy the feeling of consuming bulk but resent the texture. Expectations alone may turn a utility into a disutility. This can be depicted by a person missing his lunch and enjoying to its fullest extent the bulk characteristic contained in a sandwich. Suddenly he recalls that his favorite meal awaits him that evening when he returns from work. Is it still obvious that the utility of the bulk characteristic of the sandwich is continually positive?

---

[1] A consumer facing an income-price situation which gives rise to vectors d, g, and c, for example, is inefficient if he purchases any amount of good Z regardless of his utility function. It can therefore be predicted that efficient consumers will have zero demand for good Z at that price.

[2] Point k in Figure 2 is analogous to point G_1 in Figure 6.3, Lancaster (1971, p. 97), and to point A in Figure 5, Lancaster (1966a, pp. 149–50), when the frontier becomes G_1G_2 and $D'''C$, respectively.

[3] Though the Lancaster model allows for *objectively* negative utility characteristics, it precludes the possibility that a generally desirable characteristic may at some subjective point contain negative marginal utility.

It is difficult to conceive of goods which do not possess characteristics with negative marginal utility while still yielding a net positive marginal utility to the consumer. The common characteristics of bulk, saltiness, sweetness, adventure, usually by their very nature contain positive marginal utility but eventually the marginal utility becomes negative. The point at which it becomes negative is clearly subjective and depends on the consumer's preference function. Consumer *A*, for example, may prefer two spoons of sugar with his coffee while Consumer *B* likes his coffee black. The sugar or sweetness characteristic will be considered a positive marginal utility characteristic (up to two spoons of sugar per cup) by Consumer *A* while containing disutility for Consumer *B*. It is quite possible that Consumer *A* likes his tea without sugar while Consumer *B* likes his tea to be sweet. To accept the *NNU* assumption would very severely restrict the applicability of Lancaster's model. Rejecting this assumption it can be shown that point *c* in Figure 2 is not necessarily preferred by the efficient consumer to point *k*.

Consider the following utility function *u*,

$$u = 2b - 8a \tag{1}$$

where *a* and *b* are the number of units consumed of characteristics *A* and *B*, respectively. Each unit of good *X* contains 1.2 units of *A* and 6 units of *B* and each unit of good *V* contains .2 units of *A* and 4 units of *B*. The total amount of characteristics *A* and *B* consumed with goods *X* and *V* is:

$$a = 1.2x + .2v \tag{2}$$

$$b = 6x + 4v \tag{3}$$

where *x* and *v* are the number of units consumed of *X* and *V*, respectively. By substituting (2) and (3) into (1),

$$U_{x+v} = 2.4x + 6.4v \tag{4}$$

The utility equations show constant utility to scale and constant marginal utility for each good and each characteristic. Figure 2 represents an income-price situation where the consumer's spending of his total income may result in the purchase of either ten units of *X* (point *c*), ten units of *V* (point *k*), or any linear combination of the two (line *kc*). The market price ratio of goods *X* and *V* is one. From (4) we see that $MU_v/MU_x = 6.4/2.4$ and consumer equilibrium requires the purchase of *V* only (point *k*). It is important to note that while characteristic *A* conveys disutility, each good is desirable. It is possible to construct utility functions where the utility of characteristic *A* is negative but *c* is still preferred to *k*. Those functions will be subjective and without such subjective knowledge there is no way to eliminate points such as *k* from the objective efficiency frontier. Relaxation of the *NNU* assumption will not alter Lancaster's model, it will only modify the shape of the efficiency frontier which may now have a positively sloped segment.[4] While the *NNU* assumption is not essential for the Lancaster approach, the derivation of the linear combination frontier is the very basis of his model.

III

Lancaster refers to the analogy of his approach to that of production theory. He assumes that in consumption technology, goods are the inputs and the collection of characteristics is the output. (See Lancaster (1966a, p. 133) and (1966b, p. 14).) This assumption gives the impression that the consumer's objective is to maximize the output of characteristics subject to the budget constraint on the input of goods (and the linear efficiency frontier does just that). The consumer's real objective is to maximize the utility which the characteristics yield, not the amount of characteristics per se. The proper analogy to production theory would be to assume that in consumption technology characteristics are the inputs used to produce the output of utility, while the goods are the processes by which this output is obtained.

---

[4] The frontier in Figure 2 becomes *kcd*. In Figure 6.3, Lancaster (1971, p. 97) it should be $G_3G_1G_2$ and in Figure 5, Lancaster (1966a, p. 149) it becomes $AD'''C$ instead of $D'''C$.

Lancaster's efficiency frontier is derived by a linear combination which is similar to the linear combination isoquant derived by Robert Dorfman, p. 805. The linear combination isoquant indicates the aggregate level of output obtainable by utilizing several production processes. Any given point on the isoquant indicates a given amount of each input used by the various processes. If the same total quantities of the inputs were to be used by a different process the resulting level of output would be incomparable to that of the linear combination isoquant.[5] Lancaster's approach, however, is based on just such comparisons. The derivation of the efficiency frontier presupposes the ability to compare the utility (output) of a linear combination of two separate goods (processes) with that of a third good (process). According to Lancaster, point *f*, which is obtained by a linear combination of vector *h* of good *X* and vector *i* of good *Y*, is preferable to point *g* which might be obtained by consuming good *Z* alone. Although point *f* represents a larger amount of total characteristics, the conclusion that it is preferable to point *g* (which is obtained by a different process) requires either one of the two following assumptions: 1) the utility independence of characteristics per consumption unit (*UIC*), or 2) the "mixability" of goods per consumption unit (*CU*). The *UIC* assumption means that while total utility of one characteristic may depend on the total amount of the other characteristics, it is independent of the ratio of characteristics per unit of consumption. The mixability assumption means that two different goods (such as *X* and *Y*), each containing a different ratio of characteristics, can be mixed to yield the same ratio of characteristics as a third good (*Z*) per unit of consumption.

The *CU* concept is of great importance to consumer theory. The consumption of goods and services is very seldom instantaneous. The utility derived from the consumption of a good depends on the length of time over which it is consumed and the manner in which it is consumed. The utility derived from drinking an average amount of one fifth of whiskey per week, for example, will depend on the time distribution of its consumption. Drinking a full fifth every Sunday and none the rest of the week is most likely to yield a different level of utility per fifth a week than having a couple of drinks each day. The utility derived from consuming an apple is a function of how the apple is to be consumed: consuming the apple in five minutes by taking ten equal-size bites every thirty seconds is likely to yield a different level of utility than taking the same size bite every thirty minutes, or consuming it by taking equal bites every five seconds for five minutes. The theory of consumer behavior implicitly assumes that the consumer distributes his consumption of every good in such a "time-manner" combination that will maximize his utility, i.e., the consumer is assumed to be time-manner efficient. The utility of any individual is, therefore, a function not only of the quantities of each good he consumes but also of the time-manner coefficient of each good. The time-manner coefficients are in turn a function of the quantities consumed. A consumer having only one apple (or drink) a day will probably have a different optimal time-manner coefficient than the one he would have if the price were to decline so that he would be consuming three apples (or drinks) a day. The *CU* refers to the unit of consumption which maximizes consumer's utility. In the above example it would be measured in terms of the optimal bite-size of the apple. The *CU* is clearly subjective. It is a function of taste, the quantity consumed of each good, expectations, etc.

---

[5] The output of a process utilizing ten units of labor and ten units of capital, for example, is unlikely to be equal to the sum of the outputs produced by one process utilizing ten units of labor and zero capital and another process utilizing ten units of capital and zero units of labor.

The mixability assumption is valid only in respect to a very small portion of goods consumed. The validity of the model as a general theory must rest on the *UIC* assumption. This implies that the individual is indifferent to whether he consumes one very sweet apple and one without any sweetness (but otherwise identical) or two mildly sweet apples, as long as the sum of sweetness and all other characteristics are the same. Or one rare and cold steak with two units of spices and one very hot well-cooked steak without any spices should give the same satisfaction as two warm medium-cooked steaks each containing one unit of spices. Or driving one hour in a car which is uncomfortable (or unsafe) and one hour in a car which is very comfortable (or safe) gives the same utility as driving two hours in a moderately comfortable (or safe) car, so long as the total amount of each characteristic is the same.[6] Or only inefficient consumers (or people who enjoy making them) would consume salads. The total amount of characteristics is the same whether the fruits or vegetables are consumed separately or as a salad. The preparation of a salad requires time and effort which is equivalent to paying a higher price for the salad than for the fruits or vegetables of which it is composed. Therefore, the vector representing the salad should be below Lancaster's efficiency frontier.

The above examples clearly indicate the invalidity of the *UIC* assumption. Consumers do care about the distribution of each characteristic per consumption unit (*CU*). The *CU* differs from good to good and depends on the subjective taste of the consumer. The utility of most goods and most characteristics depends on the ratio of characteristics per *CU* and not merely on their total amount. The quality of combining different characteristics in different ratios per *CU* is what gives goods their uniqueness. Upon relaxing the *UIC* assumption as a general phenomenon, the Lancaster analysis breaks down. Consider a total utility function which is a linear combination of the utility derived by the different processes (goods), and the utility function of each process is of the Cobb-Douglas type.

$$U = \sum_{i=1}^{n} U_i \tag{5}$$

$$U_i = 10a_i^{.5}b_i^{.5} \tag{6}$$

where U_i is the utility of the ith process (good) and a_i and b_i are the number of characteristics A and B, respectively, in the ith process. The utility function in our example[7] is:

$$U = U_X + U_Y + U_Z \tag{7}$$

assuming

$$a = 1.2x + 6y + 3z \tag{8}$$

$$b = 6x + 1.2y + 3z \tag{9}$$

where x, y, and z are the number of units consumed of goods X, Y, and Z, respectively. Point f in Figure 2 is obtained by consuming five units of X and five units of Y. The total number of characteristics is 36 units of A and 36 units of B. Point g is obtained by consuming ten units of Z. The total amount of A is 30 and the total amount of B is 30. From the utility functions and equations (8) and (9) it is possible to compare the utilities at points f and g.

$$\begin{aligned} u_f = u_x + u_y &= 10(1.2x)^{.5}(6x)^{.5} \\ &\quad + 10(6y)^{.5}(1.2y)^{.5} = 268.3 \end{aligned} \tag{10}$$

$$u_g = u_z = 10(3z)^{.5}(3z)^{.5} = 300 \tag{11}$$

---

[6] The last example differs from the one given by Lancaster (1966b, p. 21) for products that cannot be utilized in combination. Here it is assumed that the consumer may use them in combination by renting the cars.

[7] To simplify we assume that the utility of each characteristic is positive, which excludes good V from any consideration.

Point g which is obtained by consuming Z is preferable in this case to point f which is achieved through a linear combination of X and Y. The comparison between the utility at f and that of g is therefore subjective since it assumes a particular type of utility function—the *UIC* assumption.

The indifference curves in Figure 2 were derived from equation (6) where only one single process is utilized.

$$U = 10A^{.5}B^{.5} \tag{12}$$

and along any indifference curve

$$dU = 0 = \frac{5B^{.5}}{A^{.5}}dA + \frac{5A^{.5}}{B^{.5}}dB \tag{13}$$

and the slope of each indifference curve is

$$\frac{dA}{dB} = -\frac{A}{B} \tag{14}$$

The indifference curves in Figure 2 are, therefore, convex to the origin.

Each indifference curve is meaningful only when each point on the curve is achieved by a single process. Any point on the same indifference curve may reflect a different level of utility if obtained through a linear combination rather than a single process. Point f, for example, is on indifference curve I_4 only if obtained by consuming good Z alone. The utility at point f if obtained through a linear combination (of points h and i) is, in the above example, the same as that of points c or d, i.e., the same as that of indifference curve I_2 which is derived for a single process. No objective judgment is possible about the utility ranking of various bundles of characteristics when they are achieved through different linear combinations. The Lancaster linear combination line dc is a "characteristics possibility frontier" rather than an efficiency frontier. Nothing can be said in terms of consumer efficiency unless the goods are known to be mixable or the consumer's utility function is given. The Lancaster efficiency frontier is objective only under certain restrictive assumptions. The "new approach" thus becomes an interesting and important special case of consumer choice rather than a general model of consumer demand.

A Note on Uncertainty and the Evaluation of Public Investment Decisions

By ESTELLE JAMES*

The optimal handling of risk by the government continues to be a subject of controversy. Some economists maintain that the government should base its decisions on prices prevailing in the market, while others hold that the appropriate social risk premium is lower than the private. Early proponents of the latter viewpoint pointed to the advantages of diversification and risk pooling from which large organizations such as the government benefit. In a recent major contribution, Kenneth Arrow and Robert Lind have added another justification: by spreading the risk across large numbers of people, the government reduces the overall cost of bearing risk to zero in the limit.[1]

Risk pooling applies in the many-project case, regardless of the number of investors. Risk spreading applies in the many-investor case, regardless of the number of projects. The purpose of this paper is to explore the relationship between these two arguments and their implications for the much debated issue of whether investment projects undertaken by the government should be evaluated individually or as a group.

Section I analyzes the risk premium as arising from two characteristics of a gamble: its scale and its dispersion. The Arrow-Lind argument for a low social risk premium stems from a scale effect, while the risk-pooling argument stems from a dispersion effect. For both, there may be an inconsistency between the piecemeal and global evaluation of projects, but the nature of the conflict is reversed in these two cases. The effect on dispersion of risk pooling may lead the government to *accept a group* of projects which were *individually rejected.* On the other hand, the scale effect may lead the government to *reject an entire group* of projects which were *accepted individually* due to risk spreading. This inconsistency is avoided and piecemeal and global decisions will coincide when the scale effect (risk spreading) dominates in the evaluation of individual projects and the dispersion effect (risk pooling) dominates in the group evaluation. Section II develops this theme further, using diagrammatic techniques.

Section III investigates the necessary and sufficient assumptions for another Arrow-Lind finding—that if the time-state preference approach is used, the value of an investment to the individual depends only on its expected return. This finding is shown to hold only under rather strong restrictive conditions which were not explicitly specified in their paper.

I

A. *Risk Spreading and the Scale Effect for Individual Projects*

The Arrow-Lind argument may be summarized as follows: Assume there are n identical people in an economy, each with disposable income represented by A. A project is under consideration which would yield a return of $\overline{B}+X$, where $\overline{B}$ is the expected net benefit and X the random part with mean $u_X=0$. The risk cost attached to this project if undertaken by one person (i.e., the amount he would willingly pay to avoid the risk represented by X) may be denoted k_X, and for $k_X>\overline{B}$, he would not accept the project. If the risk is shared among n people, each person's part of the return becomes $(\overline{B}+X)/n$. The corresponding risk cost (i.e., the amount an individual would pay to avoid the risk represented by X/n) becomes $k_{X/n}$ for one person and $nk_{X/n}$ for all, while the expected social return remains $\overline{B}$. For large n, $nk_{X/n} < k_X$, and further, $nk_{X/n} \rightarrow 0$ as $n \rightarrow \infty$. Therefore, we may have $k_X > \overline{B} > nk_{X/n}$, in which case the project should be undertaken collectively, although it would not be undertaken privately.

---

* Professor of economics, State University of New York, Stony Brook. I would like to thank my colleagues, R. Kihlstrom, E. Neuberger, and M. Nienhaus for their helpful comments on an earlier version of this paper.

[1] See Arrow and Lind for the risk-spreading justification. The private market argument is stressed by Jack Hirshleifer and the risk pooling argument was set forth by Paul Samuelson and William Vickrey, among others.

We may restate this conclusion in terms of a scale effect and a dispersion effect on risk costs, two concepts which will be developed further in this note. Define the scale of a gamble in terms of the maximum possible positive and negative values of the random variable, i.e., its range. Two random variables Y and Z with means $u_Y = u_Z = 0$, maximum positive values Y_1 and Z_1 and minimum values Y_2 and Z_2 are said to have the same scale if $Y_1 - Y_2 = Z_1 - Z_2$. Define the relative dispersion of a gamble in terms of the probabilities π attached to any two values of the random variable. Two random variables Y and Z are said to have the same relative dispersion if $\pi_{qY_1} = \pi_{qZ_1}$ and $\pi_{qY_2} = \pi_{qZ_2}$, where q can take on any value between 0 and 1 and π_{qY_1} signifies the probability that $Y = qY_1$.

In the Arrow-Lind example, where the random variable simply becomes X/n instead of X, the scale of the gamble has been multiplied by $1/n$ while the relative dispersion has remained the same, i.e., $\pi_{qX_1} = \pi_{q(X/n)_1}$ and $\pi_{qX_2} = \pi_{q(X/n)_2}$. In such a case, Arrow-Lind have shown the risk premium an individual imputes to the smaller gamble is less than $1/n$th his risk premium for the larger gamble. The expected return, however, has only decreased from $\overline{B}$ to $\overline{B}/n$; i.e., net benefits fall in proportion with scale while risk costs fall faster than scale. This *pure scale effect* on risk costs accounts for the advantages of risk spreading demonstrated by Arrow-Lind.

Arrow-Lind prove their point mathematically, but it is worthwhile inquiring into its intuitive rationale. Risk aversion is usually assumed to stem from diminishing marginal utility of income, so that in a fair gamble the utility of the potential income gain is less than the utility of the potential loss. For example, in Figure 1 the slope of the utility function over AY_1 is less than that over Y_2A; let us call w_{kY} the utility difference associated with the fair gamble of scale $Y_1 - Y_2$ leading to risk premium k_Y. If we now double the scale of the gamble, say from $Y_1 - Y_2$ to $Z_1 - Z_2$ (with its relative dispersion unchanged), we find an even greater difference between the utilities of the incremental income gain and loss, i.e., the difference in slope between Y_1Z_1 and Z_2Y_2 is larger than the difference between AY_1 and Y_2A. Hence, the total utility difference has more than doubled; $w_{kZ} > 2w_{kY}$. In general, when the scale of a gamble is multiplied by a factor p, the utility difference changes more than p. This in turn suggests that the risk premium changes more than p.[2] Applying this analysis to the Arrow-Lind case, when scale is multiplied by $1/n$, $X \rightarrow X/n$, $\overline{B} \rightarrow \overline{B}/n$ but $k_X \rightarrow k_{X/n} < k_X/n$, so for large n, $k_{X/n} < \overline{B}/n$ and $nk_{X/n} < \overline{B}$ even if $k_X > \overline{B}$.

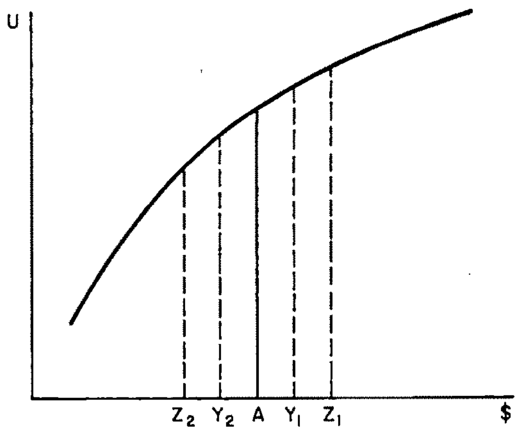

FIGURE 1. UTILITY, RISK AVERSION, AND SCALE

It should be noted that the same effect could be achieved by a single individual without any collective action for projects characterized by perfect divisibility and constant returns. Thus, risk spreading leads to a divergence between social and private decisions about risk projects only in the absence of these characteristics.

---

[2] This explanation for the scale effect also holds in the case of concave utility functions and preference for gambling: the premium such an individual would be willing to pay for the opportunity to gamble would then increase faster than the scale of the gamble.

B. *Risk Spreading, Scale, and Global Evaluations*

While the advantages of risk spreading hold when each (indivisible) project is evaluated individually, it seems reasonable to ask whether the result arrived at by marginal decision making is globally optimal. To explore this question, let us assume that m projects are under consideration, each having expected benefit $\overline{B}$ and random return X with mean $u_X=0$. The risk cost to a single person undertaking one of these projects is k_X; if shared among n identical people, the risk cost per person is $k_{X/n}$. As above, $k_X>\overline{B}>nk_{X/n}>0$ for large but finite n; thus, each project is acceptable on a shared basis only, and all m projects are undertaken collectively.[3] Is society satisfied with this result overall?

Suppose first that the returns of these projects are perfectly correlated; that is, they depend on the state of the world such that for any given state all projects will yield exactly the same return. The total expected return for each person from the m projects taken as a group is now $m(\overline{B}/n)$, the random part is $m(X/n)$, and the corresponding risk premium is $k_{mX/n}$. If $m=n$, these expressions may be simplified: $m(\overline{B}/n)=\overline{B}$; $m(X/n)=X$; and $k_{mX/n}=k_X$. That is, the risk attached by the individual to the bundle of n shared correlated projects is k_X, exactly the same as the risk associated with one whole project. We know that the latter is greater than $nk_{X/n}$, which we may now interpret as the sum of the separate risk premiums imputed by the individual to each of the n shared projects. We also know that k_X exceeds the expected return $\overline{B}$. The larger number of piecemeal collective investment decisions has cancelled the scale effect. Consequently, when the individual reevaluates his position globally, he finds himself in exactly the same choice situation he was in initially when, quite rationally, he preferred not to invest.

There exists, in other words, a possible inconsistency between marginal and global decisions, due to the scale effect. Each shared project is acceptable on its own, but if the entire bundle is reconsidered, a typical individual would prefer to eliminate them all. The larger m is relative to n, the larger $k_{mX/n}$ is relative to $mk_{X/n}$ and the greater the likelihood that marginal decisions based on risk spreading will not lead to a preferred outcome globally.

C. *Risk Pooling and the Relative Dispersion Effect*

Is there any way out of this dilemma? In some cases yes, but only if the projects are independent so that there are gains from risk pooling, which changes the relative dispersion of returns.

Suppose then that the returns to the m projects are independent, rather than being perfectly correlated. If $m=n$, the expected return to each person remains $n(\overline{B}/n)=\overline{B}$; the random term we shall denote as $\sum(X/n)$. We cannot simply say that $\sum(X/n)=X$, since the relative frequency distributions of these variables differ. Specifically,

$$\pi_{q(\Sigma X/n)_1}>\pi_q X_1 \quad \text{and} \quad \pi_{q(\Sigma X/n)_2}>\pi_q X_2$$

for q near 0 and vice versa for q near 1. That is, the probability attached to $\sum(X/n)$ is higher for values near $u_X=0$ and lower for values far from zero than is the probability attached to X. The scale of $\sum X/n$ (n pooled shared projects) is, however, the same as that of X (a single nonshared project), since $(\sum X/n)_1=X_1$ and $(\sum X/n)_2=X_2$. Thus we have isolated the *pure dispersion effect*, ordinarily associated with risk pooling. As discussed in the risk-pooling literature, the denser frequency distribution of $\sum X/n$ means that $k_{\Sigma X/n}<k_X$.

---

[3] We are assuming that the risk cost $k^i_{X/n}$ is the same for all projects $i=1, \ldots m$ and, further, does not change as expected income changes when some of the projects have been undertaken. This simplification is made for expositional purposes; the argument still holds when $k^i_{X/n}$ differs or changes, so long as $k^i_X>\overline{B}$ but $nk^i_{X/n}<\overline{B}$ for all i. Likewise, the assumptions that $\overline{B}$ is the same for all i and later that $m=n$, are made for expositional convenience and are not essential to the main result—that there may be an inconsistency between global and marginal decision making due to the scale effect. The assumption of perfect correlation is, however, crucial as will be shown later.

D. *Pooling Shared Risks: Scale and Dispersion Effects Combined*

We have found that because of the pure scale effect, $k_X > \bar{B} > nk_{X/n}$. We have also found that because of the pure dispersion effect, $k_{\Sigma X/n} < k_X$. It remains now to compare $k_{\Sigma X/n}$ with $nk_{X/n}$ and $\bar{B}$.

In making this comparison, both the scale and dispersion effects must be taken into account. As we have observed, the scale of $\sum X/n$ (n pooled shared projects) is n times the scale of X/n (a single shared project) and therefore $k_{\Sigma X/n}$ may be greater than $nk_{X/n}$ and $\bar{B}$. In this sense, risk pooling introduces a scale effect, which increases the risk premium. On the other hand, $\sum X/n$ has a denser relative probability distribution than X/n and on this account $k_{\Sigma X/n}$ may be smaller than $\bar{B}$ and $nk_{X/n}$. While both $nk_{X/n}$ and $k_{\Sigma X/n} \to 0$ as $n \to \infty$, the former because of the scale effect and the latter because of the dispersion effect, we may for a given finite n have $k_{\Sigma X/n}$ greater or smaller than $nk_{X/n}$ and $\bar{B}$, depending on the relative strength of these two effects.

If the scale effect dominates, we will have $k_X > k_{\Sigma X/n} > \bar{B} > nk_{X/n}$. Global and marginal decisions still conflict and an entire group of individually acceptable projects may be rejected globally. If, on the other hand, the dispersion effect is sufficiently strong, we will have $k_X > \bar{B} > k_{\Sigma X/n} \lessgtr nk_{X/n}$. Since $k_{\Sigma X/n}$ is a declining function of n when the projects are independent, we can always find an n large enough to bring about the latter case and avoid the inconsistency between global and marginal decisions described above.[4]

II

This analysis may be illustrated diagrammatically, as follows. For any given person, the risk cost k attached to a gamble represented by a random variable Y with mean $u_Y = 0$ depends on two characteristics of Y: its scale and its relative dispersion. If the latter is held constant, k_Y is an increasing function of scale and the second derivative is also positive. If the distribution of Y changes, we get an entirely different function which for "better" distributions lies completely below the first; in Figure 2, $k^B < k^A$ for any given scale. Thus, we have a whole family of curves depicting k as a function of scale, each curve associated with a different relative dispersion of Y.

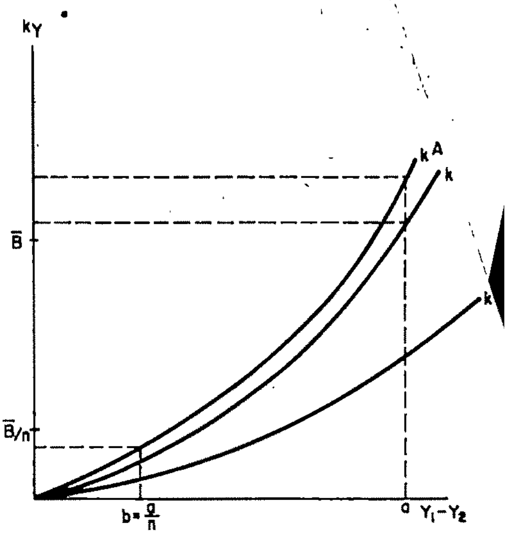

FIGURE 2. RISK COST AS A FUNCTION OF SCALE AND RELATIVE DISPERSION

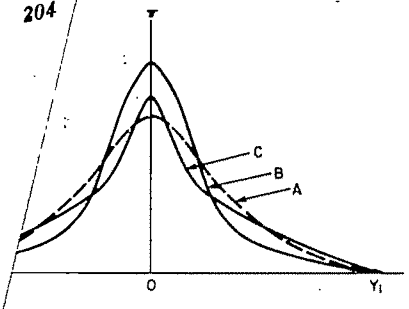
While scale can easily be quantified as $Y_1 - Y_2$, the ordering of the relative dispersion depends on subjective rather than objective evaluations. That is, different individuals may have different preference orderings for the various possible distributions and even if they agree on ranking they may disagree on the absolute value of the change. For example, in Figure 3 some individuals might rank distribution A over distribution C and others vice versa. A shift from A to B, on the other hand, would be deemed an improvement by all risk averters, but they might disagree on the size of the gain.

Now, in the initial situation described by Arrow-Lind, the investor faces random variable X with scale a and relative dispersion A such that $k_X > \bar{B}$; the project is not accepted (see Figure 2). Risk spreading among n people moves him to random variable X/n with scale $b = a/n$ and dispersion

---

[4] For a closely related discussion of $k_{\Sigma X/n}$ see Richard Kihlstrom and Mark Pauly.



3. DIFFERENT RELATIVE DISPERSIONS FOR SAME SCALE

which $k_{X/n}<\overline{B}/n$; the project is ac- When n perfectly correlated pro- are undertaken and shared, the scale ts to a, the dispersion still unchanged; $_{/n}=k_X>\overline{B}$ and the investor regrets his ecision to accept the entire bundle.

If instead the projects are statistically independent, the pooling process changes the distribution and hence places the investor on another curve, k^B or $k^{B'}$ with random variable $\sum X/n$ at scale a. Since the new relative dispersion is unambiguously better than the old, both k^B and $k^{B'}$ are lower than k^A. However, in the latter case the scale effect dominates at a so $k_X>k_{\Sigma X/n}>\overline{B}>nk_{X/n}$. If on the other hand the individual has a stronger preference for B over A, k^B becomes relevant; the dispersion effect outweighs the scale effect sufficiently to make $k_X>\overline{B}>k_{\Sigma X/n}\lesseqgtr n k_{X/n}$. The larger the number of pooled independent projects, the more likely that this will be the case. In other words, piecemeal decisions based on risk spreading will lead to a correct global outcome if and only if sufficiently large gains from risk pooling are also present, when the investments are reevaluated as a group.

III

The Arrow-Lind paper also proved that if the time-state preference approach is used and a perfect market exists for contingent claims in each possible state of the world, the value of an investment to an individual depends only on its expected return. This runs counter to the usual presumption that the value of a project is a function of the state-distribution of its returns and the utility functions, subjective probabilities and prices associated with different states of the world.

Arrow-Lind derive their surprising conclusion by moving from a situation where each state is treated separately to a situation where states are aggregated according to utility functions and returns. A crucial step in this transition involves their statement that "... the allocation X_{itq} depends only on t, i.e., is the same for all states in E_t for any given t" (p. 369) so that $\partial U_{is}/\partial X_{isq}$ in equation (3) may be replaced by $\partial U_{it}/\partial X_{itq}$ in equation (9).[5] Upon closer examination, it appears that this procedure is valid if and only if two additional assumptions are made about initial endowments and subjective probabilities.

The following observations are suggestive of this finding. If $X_{irq}=X_{isq}$ for two states r and s in a given E_t and for all individuals $i=1,\dots I$, then $\sum_i X_{irq}=\sum_i X_{isq}$. Since by definition, the total consumption claims in each state cannot be changed by trading, $\sum_i X_{irq}=\sum_i \overline{X}_{irq}=\sum_i \overline{X}_{isq}=\sum_i X_{isq}$. *That is, the total initial endowments* $\sum_i \overline{X}_{irq}$ *and* $\sum_i \overline{X}_{isq}$ *would have to be the same for all states with the same utility function; the total number of available consumption units could not differ for two states which happen to have the same* U_{is}.

---

[5] In order to save the reader's time, the symbols used in Arrow-Lind paper and in this section of my note are defined below:

X_{isq} = the equilibrium claim of individual i in state s in time period q+1.
$\overline{X}_{isq}$ = the initial (consumption claim) endowment of individual i in state s in time period q+1.
E_t = a partition of all states of the world such that, for all s in any given E_t all utility functions U_{is} are the same for any individual i; this partition is assumed to be the same for all individuals.
F_u = a partition of all states of the world such that, for all s in any given F_u, the returns on a particular investment project are the same.
E_{tu} = the set of all states of the world which lie in both E_t and F_u.
P_{sq} = the present value of a single commodity unit at time q+1, given state s.
π_u = the probability of F_u, assumed to be the same for all individuals.
π_{is} = the subjective probability that individual i assigns to the occurrence of state s.

Also, if $X_{irq}=X_{isq}$ and $U_{is}=U_{ir}$, then $P_{sq}/P_{rq}=\pi_{is}/\pi_{ir}$, $i=1,\dots I$, by Arrow-Lind's equation (4) which states that

$$\frac{P_{sq}}{P_{rm}}=\frac{\pi_{is}}{\pi_{ir}}\,\frac{\partial U_{is}/\partial X_{isq}}{\partial U_{ir}/\partial X_{irm}}$$

That is, all people must have equal, exogenously given, subjective relative probabilities for any two states in a given E_t. Neither of these assumptions is explicitly specified in the Arrow-Lind model.

We can show more formally that the equal endowments and relative probabilities assumptions constitute necessary conditions for the desired results as follows: If subjective relative probabilities differ among people, relative marginal utilities must also differ in equilibrium, by equation (4). Hence $X_{isq}\neq X_{irq}$, $\partial U_{is}/\partial X_{isq}\neq\partial U_{ir}/\partial X_{irq}$ and both cannot be replaced with $\partial U_{it}/\partial X_{itq}$ for at least some individuals. If relative probabilities are the same for all people but $\sum\overline{X}_{isq}>\sum\overline{X}_{irq}$, $(\partial U_{is}/\partial X_{isq})/(\partial U_{ir}/\partial X_{irq})$ must be the same for all by equation (4), so all people must end up with $X_{isq}>X_{irq}$ and $\partial U_{is}/\partial X_{isq}<\partial U_{ir}/\partial X_{irq}$; therefore we could not replace both with the expression $\partial U_{it}/\partial X_{itq}$.

The equal endowments and relative probabilities assumptions are also sufficient conditions for these results. Suppose that for s and r in a given E_t, $\sum\overline{X}_{irq}=\sum\overline{X}_{isq}$ and π_{is}/π_{ir} is the same for all people. Because of the latter, $(\partial U_{is}/\partial X_{isq})/(\partial U_{ir}/\partial X_{irq})$ must also be the same for all people since they face the same prices. If $\partial U_{is}/\partial X_{isq}\lesseqgtr\partial U_{ir}/\partial X_{irq}$, then $X_{irq}\lesseqgtr X_{isq}$ for all i so that $\sum X_{irq}=\sum\overline{X}_{irq}\lesseqgtr\sum X_{isq}=\sum\overline{X}_{isq}$. This, however, would contradict the equal endowments assumption. Therefore, to satisfy this assumption, $X_{isq}=X_{irq}$ for all i, $\partial U_{is}/\partial X_{isq}=\partial U_{ir}/\partial X_{irq}$, and $P_{sq}/P_{rq}=\pi_{is}/\pi_{ir}$.

Thus, if these restrictions are made on the magnitudes of the initial endowments and the subjective probabilities, the equilibrium X_{isq} must be identical for all states s within a given E_t, $\partial U_{is}/\partial X_{isq}$ may be replaced by $\partial U_{it}/\partial X_{itq}$ and the market-clearing set of relative prices must equal the relative probabilities. If these restrictions are not made, the allocation of X_{isq} must vary for different states in a given E_t, $\partial U_{is}/\partial X_{isq}$ could not simply be replaced by $\partial U_{it}/\partial X_{itq}$, and relative prices depend on both probabilities and marginal utilities. While Arrow-Lind specify various assumptions regarding the uniformity of π_{it} for all people and all t and the independence of returns on this investment from previous returns, the equal endowments and relative probability requirements are additional. They constitute both necessary and sufficient conditions for the Arrow-Lind results.

The time-state preference approach suggests that the different state preferences and their prices must be used in evaluating an investment since the returns may be concentrated in states with 1) low (high) initial endowments, or 2) high (low) utility functions, or 3) high (low) probabilities and therefore high (low) time-state prices. The Arrow-Lind analysis has shown that when the first two possibilities are assumed away and certain restrictions are placed on the probability structure only the expected return need be taken into account in making a risky investment decision.

Tax Policy and Investment: An Analysis of Survey Responses

By ROBERT EISNER AND PATRICK J. LAWLER*

Economic policy in the United States in recent years has included tax measures designed to affect the level of business investment. These have taken several forms: accelerating rates of tax depreciation on capital goods, thus lowering the present value of expected tax liabilities and actually decreasing annual tax payments; tax "credits" amounting to subsidies for the purchase of equipment; and alterations in business income tax rates. With additional acceleration of tax depreciation in the "Asset Depreciation Range" system and reenactment of an equipment tax credit in 1971, and recent proposals for suspension and then for increases in the credit, the issues are particularly current.

A number of analyses have attempted to estimate the effects of investment tax incentives by incorporating their presumed implications in more general variables, such as the cost or "rental price" of capital, and estimating the parameters of these more general variables.[1] In some instances attempts have been made to estimate effects more directly, either entering tax rates separately or isolating the specific changes in more general variables which have been due to the tax measures.[2] Our efforts here are directed primarily at what business respondents in McGraw-Hill surveys *said* a number of tax measures would do or had done to their anticipated or actual capital expenditures and comparing these with several econometric projections. We shall also report briefly on inconclusive results of inclusion in general investment functions of the survey responses as to anticipated or actual effects of the tax measures on expenditures.

I. The Survey Data

The current analysis utilizes McGraw-Hill capital expenditure surveys of firms in nonfinancial industries. The following questions in the 1963, 1964, 1965, 1966 (fall), and 1968 surveys deal with the effects of tax measures on investment.[3]

In the survey for the spring of 1963, McGraw-Hill included the question, "Of the total amount you now plan to invest in 1963, roughly how much is due to: a) New depreciation schedules? ___ %; b) Tax credits for new equipment? ___ %." In the survey of the spring of 1964, a similar question referred to plans to invest in 1964.

The spring survey of 1965 asked, "Of the amount you invested in 1964, roughly how much more did your company spend than it would have because of: a) Reduction in corporate tax rate? ___ %; b) Revised depreciation schedules? ___ %; c) Tax credits for new equipment? ___ %."

Then in the fall of 1966, McGraw-Hill asked, "How much have you reduced your 1967 capital investment plans because of suspension of: a) Investment tax credit? \$___; b) Accelerated depreciation on structures? \$___."[4]

Equipment tax credit	1963	2.8 (337)	1.4 (274)	4.4	0.6[d]		
New depreciation guidelines	1964	2.8 (301)	1.3 (273)	—	—	—	—
Equipment tax credit	1964	1.1 (299)	0.8 (271)	—	—	—	—
Proportion of actual capital expenditures due to:							
Corporate income tax reductions	1964	0.8 (275)	0.5 (245)	−0.4[c]	0.05	—	3.5
New depreciation guidelines	1964	1.5 (273)	0.9 (243)	2.2	1.0[d]	0.9	
Equipment tax credit	1964	1.3 (272)	1.1 (242)	6.8	3.9[d]		
Proportion anticipated capital expenditures reduced due to:							
Suspension of accelerated depreciation on structures	1967	−0.7[e] (331)	−0.1[e] (332)	−1.4	—	−2.8	—
Suspension of equipment tax credit	1967	−2.2[e] (331)	−0.7[e] (339)	−6.8	—		
10 percent corporate tax surcharge	1968	−1.6 (281)	−0.2 (160)	—	—	—	—

[a] For data base, see Appendix.

[b] Number of responses in parentheses.

[c] Assumed no effects on output.

[d] Bischoff's estimates relate only to equipment. If the depreciation guidelines and equipment tax credit had no effect on expenditures for structures the implicit estimate of their percent effect on all capital expenditures would be roughly two-thirds of the figure shown.

[e] McGraw-Hill reported, as to the aggregate, that suspension of accelerated depreciation on structures and of the equipment tax credit had reduced fall 1966 capital expenditure plans by $1.5 billion out of a total of some $63.4 billion (Press release, February 10, 1967, "McGraw-Hill's Special Check-up on 1967 Investment Plans") or about 2.4 percent, a somewhat higher figure than the weighted mean total of 0.8 percent but less than the simple mean total of 2.9 percent calculated from our partial sample.

Finally in the spring of 1968, we have the question, "If the proposed 10% surcharge on corporate income taxes is enacted, how much do you estimate this will reduce your capital spending plans for 1968? ___ %."

Table 1 presents information regarding all of the responses available. Working with the raw means of survey answers as to the percent effect of the various measures on anticipated or actual expenditures, we find respondents generally indicating small movement in the presumably correct directions, and usually somewhat larger effects from

---

capital expenditures reported in answer to an accompanying question, thus securing observations in ratio form comparable to those relating to questions on the other surveys.

liberalized depreciation than from the tax credits for new equipment.[5] Thus the ununweighted mean proportion of anticipated investment in 1963 attributed to the new depreciation schedule was 4.2 percent while that attributed to tax credits for new equipment was 2.8 percent. The similar question in 1964 again shows a larger amount of anticipated investment attributed to liberalized depreciation than to the tax credit but, interestingly, considerably smaller proportions for both than in the previous year.

That this is so, despite the cumulative gains from continued accelerated depreciation and the fact that 1964 investment should have reflected the lagged results of earlier as well as current stimuli, raises some question as to the internal consistency of the responses. This concern may be heightened by the *ex post* response in early 1965 regarding actual 1964 expenditures. For the proportion then attributed to the revised depreciation schedule was only 1.5 percent, little more than half of the 2.8 percent which had been indicated in previous anticipations of those expenditures and little more than a third of the 4.2 percent mean figure noted with regard to the 1963 anticipations.

The suspension of accelerated depreciation on structures instituted in the fall of 1966, presumably to last until the end of 1967, was reported on average to have reduced 1967 capital investment plans by only 0.7 percent. In this case, where depreciation related only to structures, the equipment tax credit seemed more potent, inasmuch as the mean percentage reduction in investment plans as a consequence of its suspension was 2.2 percent.

In early 1965 the effective reduction in 1964 corporate tax rates of 3.8 percent, or 2 percentage points, was reported to have brought about an average increase of only 0.8 percent in 1964 investment, although profits before taxes were between two and three times investment. Thus each dollar of tax reduction was reported to bring in the neighborhood of some 20 cents in added capital expenditures. The proposed 10 percent corporate tax surcharge, raising the effective tax rate by some 4½ percentage points, was estimated in early 1968 to reduce capital spending plans for 1968 by a mean figure of 1.6 percent, implying again only about a 20 cent reduction in corporate capital expenditures for each dollar of increased corporate taxes.[6]

Both the accuracy and consistency of these responses is questionable. The bulk of individual survey answers as to percentage effect were "zero." There is no evidence that lack of information was translated into zero responses, but to the extent that it was, means would of course be biased toward zero and effects of tax measures underestimated. Running the other way, a number of relatively extreme observations, including figures of "+ 100 percent," contribute to higher means and make the differences between means of doubtful significance. Large percentage responses seem to come predominantly from small firms. We have consequently calculated ***weighted*** means of survey responses, and the estimated incentive effects, measured as total indicated changes in expenditures divided by total expenditures, are universally more moderate. Thus the anticipated total effect of depreciation guidelines in 1963 amounted to 1.9 percent of total expenditures, rather than the 4.2 percent which was the unweighted or simple mean of survey percent responses. For the equipment tax credit, a weighted mean of 1.4 percent for anticipated effects in 1963

---

[5] This despite estimates indicating that the present value of tax advantages due to the equipment tax credit was, for reasonable rates of discount, greater than that due to the depreciation guidelines, a fortiori, since it turned out that many firms had been "liberalizing" their depreciation before the new guidelines and hence had less additional gain. Hall and Jorgenson, pp. 50, 51, 55, estimate the impact on the rental price of capital as roughly one and one-half times greater for the equipment credit in 1963 and roughly two and one-half times greater in 1964, after firms were no longer required to deduct the credit from an asset's depreciable base.

[6] These figures are interestingly comparable with those of Coen (1971, p. 179). Dealing with manufacturing only, for the entire period 1954 to 1966-III, he estimated increased capital expenditures of $4.8 billion to be associated with total tax reductions of $13.7 billion, a ratio of some 35 percent.

TABLE 2—PERCENTAGE EFFECTS ON CAPITAL EXPENDITURES, SIMPLE AND WEIGHTED MEANS, VARYING AND IDENTICAL PANELS OF RESPONDENTS

				Identical Panels					
		All Observations Available		Anticipations, 1963 and 1964			Anticipated and Actual, 1964		
					Panel for Weighted Means			Panel for Weighted Means	
Expenditures	Tax Measure	Simple Means	Weighted Means	Simple Means	Simple Means	Weighted Means	Simple Means	Simple Means	Weighted Means
Anticipated for 1963	Depreciation Guidelines	4.2	1.9	4.4	2.8	1.2	—	—	—
	Equipment Tax Credit	2.8	1.4	2.6	1.2	0.7	—	—	—
Anticipated for 1964	Depreciation Guidelines	2.8	1.3	3.0	2.7	1.3	2.7	2.1	1.2
	Equipment Tax Credit	1.1	0.8	1.1	1.2	0.8	1.1	1.1	0.7
Actual, 1964	Depreciation Guidelines	1.5	0.9	—	—	—	1.5	1.5	1.0
	Equipment Tax Credit	1.3	1.1	—	—	—	1.5	1.5	1.4
Number of Respondents		[a]	[a]	217	178	178	206	182	182

[a] Varies as indicated in Table 1.

replaces the 2.8 percent unweighted mean.

Some inconsistency stems from the fact that samples were not identical from year to year (or for simple and weighted averages, because a number of observations did not include the actual dollar expenditures required in weighting). In particular, no downward trend in anticipated effects from 1963 to 1964 is apparent when we examine identical panels of respondents, as may be noted in Table 2.

It is possible to compare survey responses with *ex post* estimates derived from econometric estimates by Hall and Jorgenson, Bischoff, Klein and Taubman, and Coen. The survey responses generally indicate considerably less effectiveness of the various tax incentives, especially in terms of weighted means, than the predictions of Hall and Jorgenson. The 1964 expenditure effects viewed *ex post* come midway between those estimated by Klein and Taubman and by Coen and, for the depreciation guidelines, come quite close to those estimated by Bischoff. The largest discrepancies occur in estimates of effects of the equipment tax credit, where the econometric estimates, particularly those by Hall and Jorgenson, are much higher than the survey responses, and in the case of the short-run 1967 suspensions, where the econometric estimates are again higher. Only corporate income tax reductions, viewed as perverse or trivial in their results in two econometric estimates, appear to have greater, though still very small, effects in the surveys.

Examination by industry of the means of reported survey effects in Table 3 shows wide variations with particularly large figures reported for railroads and generally negligible ones for utilities, where the credit was only 3 percent and where indeed other evidence has indicated that capital expenditures are substantially dominated by demand and output considerations.

II. General Investment Equations Including the Tax Measure Survey Responses

The survey responses have been introduced as variables in regressions which also include the sales change, profits, and depreciation variables which were used earlier in explaining these capital expenditure data.[7] In such regressions, if a particular tax measure always had precisely the effect on capital expenditures indicated by respondents it would enter with a coefficient of unity. For example, if the respondent indicated that the new depreciation schedule increased the investment he planned for 1963 by 5 percent, an increase in planned investment by 5 percent over and above the

---

[7] The underlying investment model into which the tax policy response variables were fitted may be seen in Eisner (1967), particularly Tables 3 and 5, pp. 376 and 380.

TABLE 3—PERCENTAGE EFFECTS ON CAPITAL EXPENDITURES, SIMPLE MEANS OF SURVEY RESPONSES, BY INDUSTRY[a]

amount planned as a consequence of sales changes, profits, and depreciation charges, would imply a coefficient of unity for this response variable. If anticipated investment, despite the response, were actually only 2 percent more than indicated by the regression on the other variables, then the coefficient of the response variable would be 0.4. If the response variable in fact proved, despite respondents' claims, irrelevant to their anticipated expenditures, the coefficient should turn out to be zero. If ancipated expenditures actually moved counter to the direction indicated by the response, the coefficient would prove negative.[8]

Despite the availability of over 3600 observations, regression results were inconclusive. The depreciation guideline coefficients in firm time-series regressions, and less consistently in cross-sections and industry regressions, were roughly in the neighborhood of unity. But coefficients of the equipment tax credit variables were generally negative and of outlandish values in the time-series, while usually positive but varying substantially in cross-section regressions. Coefficients relating to the suspension of accelerated depreciation in 1966 were wildly negative (of the "wrong" sign as the variable was defined), while those of the suspension of the equipment tax credit were more often positive, but of considerable variance. Coefficients for the corporate income tax surcharge anticipated in 1967 and early 1968 were less than unity in firm time-series and cross-section regressions. In all cases standard errors were so high that parameter estimation and statistical inference were unreliable. There was, however, little in the results to suggest that the relatively moderate survey responses *underestimated* the effects of the tax measures, and the various negative coefficients raised further questions

---

[8] Algebraically, the regressions were of the form:

$$i = b_0 + \sum_{j=1}^{m} b_j x_j + \sum_{k=m+1}^{n} b_k x_k + u$$

where i = the ratio of capital expenditures, actual or anticipated, to gross fixed assets; x_j = the current and lagged relative sales change, profits and depreciation variables; and x_k = the tax policy survey response variables, expressed as ratios of actual or anticipated capital expenditures.

in some instances as to the positive effects reported.[9]

III. Conclusion

It is of course possible that survey respondents are unaware of all the influence, direct and indirect, that particular policies may have on investment. For what they are worth, however, survey responses have indicated only modest effects of tax measures designed to stimulate, or discourage, capital expenditures. Means of survey results were usually less than all except the smallest of estimates from several econometric models. Each dollar of loss or gain in taxes appeared to generate only very minor compensating capital expenditure. An attempt to estimate parameters of survey variables in general investment equations was inconclusive, but did not suggest that the survey responses, while of questionable accuracy, were underestimates.

APPENDIX

Basic data for econometric estimates in Table 1 are taken from Fromm as follows:

1. *Hall and Jorgenson*

Table 2-5 on pp. 46–47 lists gross investment divided into equipment and structures, by year:

	Equipment	Structures	Total
	(billions of 1965 dollars)		
1963	31.191	19.418	50.609
1964	35.116	20.604	55.720
1967 (est.)	39.408	24.433	63.841

Table 2-7, p. 52, lists estimated capital expenditures due to the guidelines and tax credit:

	Guidelines	Tax Credit
	(billions of 1965 dollars)	
1963	1.062	2.238
1964	1.220	3.765

Table 2-8, p. 54, reports estimated capital expenditures in 1964 due to the corporate tax cut, assuming no effect on the level of output, as −0.248 billions of 1965 dollars.

All of these incentive effects were divided by total gross investment to obtain the percentages shown in Table 1.

Table 2-11, p. 58, reports estimated effects on capital expenditures due to 1966 suspensions on the assumption that the suspensions would last through 1967:

	Equipment (tax credit)	Structures (accelerated depreciation)	Total
	(billions of 1965 dollars)		
1967	−4.062	−0.864	−4.926

Table 2-10, p. 56, reports estimated effects on capital expenditures associated with the actual abbreviated suspensions.

	Equipment	Structures	Total
	(billions of 1965 dollars)		
1967	−0.870	−0.289	−1.159

A figure for anticipated capital expenditure plans in the fall of 1966 when the suspensions were expected to last through 1967 was then obtained by subtracting from actual 1967 capital expenditures the difference between these two sets of effects. The percentages shown in Table 1 are the estimated full-term suspension effects divided by this reconstruction of anticipated capital expenditures:

$$\$63.841b - (\$4.926b - \$1.159b) = \$60.074b$$

2. *Bischoff*

Table 3-15, p. 117.

3. *Klein and Taubman*

Table 5-4, p. 238, offers gross investment estimates on the various assumptions: (1) no change in tax law; (2) changes in cash flow as a result of the equipment tax credit and the new guidelines; (3) changes in rates of return as well as cash flows:

---

[9] Detailed tabulations of some of the regression results involving observations from all of the surveys from 1955 through 1968 are available on request to the authors.

	(1) No. Change	(2) Change in cash flow only	(3) Change in rate of return and cash flow	(4) Ratio of incentive effect to investment $\frac{(2)-(1)}{(2)}$	$\frac{(3)-(1)}{(3)}$
	(billions of dollars)			(percent)	
1963	57.825	58.000	58.975	0.3	1.9
1964	63.350	63.925	66.400	0.9	4.6

Following Klein and Taubman's preference for the "cash flow only" estimate, the difference between "no change" and cash flow only, divided by the latter, is presented in our Table 1.

Table 5-2, p. 234, gives estimates of 1967 investment under the assumption of no suspension of incentives and that of a temporary suspension lasting through 1967.

No Suspension	Temporary Suspension
(billions of dollars)	
84.475	82.175

The difference in estimates divided by the temporary suspension figures yields the percentage effect.

4. *Coen*

Table 4-12, p. 178, reports actual investment in manufacturing and estimates of investment attributable to the whole package of tax incentives including the accelerated depreciation dating from 1954. Coen offers several sets of estimates. For his preferred variable-adjustment-speed model with a twelve-quarter inverted-V lag and user cost based on declining balance depreciation, the relevant figures are:

	Attributable to Incentives	Manufacturing Investment	Ratio of Incentive Effects to Investment
	(millions of 1964 dollars)		(percent)
1963	422	12,673	3.3
1964	704	14,848	4.7

Our estimate for 1963 and 1964 incentive effects exclusive of the 1954 acceleration of depreciation was obtained by subtracting the $179 million of investment Coen finds attributable to incentives for 1961, when this depreciation effect was last isolated. The figure had been decreasing according to Coen's results. Thus later estimates listed for Coen, entailing the $179 million subtraction, are probably a bit too low.

The U.S. Phillips Curve and International Unemployment Rate Differentials: Comment

By NANCY SMITH BARRETT*

A recent article in this *Review* by Robert Flanagan on international differences in unemployment experience draws some rather strong conclusions about the nature of unemployment flows in the United States relative to countries of Western Europe, as well as the relative efficiency of the *U.S.* labor market. However, since Flanagan uses a definitionally incorrect measure of one of the most important variables in his study, the interpretation of his results is at best questionable. In addition, there are data problems that Flanagan fails to address.

Using a different data source and correcting the error in the variable definition, my findings support some of Flanagan's theoretical conclusions and policy suggestions. However, there are some important differences that affect both the interpretation of the results as well as their policy implications.

I. Synopsis

Two major points stand out in Flanagan's paper. First, he contends that high unemployment rates in the United States relative to those in Western Europe (with Sweden and Great Britain used as models) reflect real differences in the tradeoff between inflation and unemployment. That is, the lower European unemployment rates are not due to a willingness to accept more inflation or to differences in statistical concepts and measurement, but signify a different and more favorable Phillips relationship.

Second, Flanagan attributes international differences in the Phillips curves to differences in the flow of workers into unemployment rather than to differences in the duration of their unemployment spells. He also suggests that these findings reflect a lower level of labor market efficiency in the United States relative to the European countries.

My analysis of the Swedish labor market compared with that of the United States supports the first proposition, but not the second. Since I used different data from Flanagan, the fact of our agreement on the first point lends independent support for some of his policy recommendations for improving the *U.S.* inflation-unemployment tradeoff. On the other hand, although I agree that there are real international differences in the Phillips tradeoff and that these are related to the components of unemployment he describes, I have found that differences in the flow into new unemployment between the United States and Sweden are substantially greater than differences in their overall unemployment rates. This implies (from Flanagan's equation (2)) that the average duration of unemployment is longer in Sweden than in the United States. As we shall see, this has important implications for the interpretation of the first finding in terms of the relative efficiency of the *U.S.* labor market as well as for stabilization policy.

II. Methodological Considerations and Data Problems

As Flanagan points out, the unemployment rate is the product of two components

$$UN = I_u D_u \tag{1}$$

where I_u is the weekly flow of individuals into new unemployment as a percent of the labor force, and D_u is the average duration of a spell of unemployment.

From a theoretical perspective, this breakdown is extremely useful for comparing the unemployment experience of different groups. A 4 percent rate of unemployment, for example, could represent a .80 percent weekly flow of individuals into new unemployment with five weeks average duration, or a .33 percent weekly flow and twelve weeks average duration. In the first case, workers become unemployed more often, but find new jobs rather quickly. In the second case, there is a greater tendency to hold on to jobs or to stay out of the labor market, but workers take more than twice as long to find a job once they become unemployed. As Flanagan observed, the determinants of I_u and D_u are different. This has implications for policies to reduce unemployment, for the welfare of the workers experiencing unemployment, as well as for the efficiency of the labor market.

---

* Professor of economics, American University. Curt Canarp and Christer Wretborn of the Swedish Labor Market Board (*AMS*) provided unpublished data on unemployment flows in Sweden.

Although it is interesting to compare the components of unemployment for different labor markets, there are complicated theoretical and technical problems associated with measuring I_u and D_u from unemployment data. Most of these stem from the ambiguous nature of the unemployment concept, particularly when applied to changes in very short periods of time. Flanagan does not discuss these difficulties at all, and the casual reader is likely to assume that his measure of I_u (he never (correctly) analyzes D_u) is as reliable as most other unemployment statistics. Using a different (and from my perspective, better) data source, I obtained different results from Flanagan. Because of this, it will be necessary to explore the data problems before discussing the data.

In the United States and Sweden[1] the official measure of unemployment is based on monthly rotating samples in which individuals are asked if they were employed, unemployed, or not in the labor force during the survey week. Those unemployed are also asked how long they have been in that status. Flanagan uses data from these monthly surveys to measure I_u, the number of persons unemployed less than one week (as a percent of the labor force). There are two major problems with this. First, because an unemployed worker must be actively seeking work, there is some technical movement in and out of the labor force from week to week for persons who want to work but temporarily stop looking. This behavior is particularly likely for women and teenagers whose association with the labor force is somewhat more tenuous than for adult males. A preferable measure of I_u would ignore these very short-run changes in labor market status.

Second, Daniel Suits and Richard Morgenstern, Hyman Kaitz (1970, 1972), and others have found that some persons experiencing one or two weeks of unemployment (exactly those represented by I_u) do not show up in the monthly surveys. This is because a person who is laid off Monday morning is not counted as unemployed during the week, although someone who entered the labor force Monday morning is. Typically, the monthly surveys show more persons with two weeks unemployment than one week. The problem cannot be solved by looking at changes in successive weeks either (as Flanagan presumably did), because more people report unemployment of 4, 8, 12, . . . weeks than is consistent with a normal pattern of unemployment survival rates. This bunching of the data around weeks that are multiples of four suggests that respondents tend to report unemployment duration in months rather than weeks.[2]

Instead of using data from the monthly survey, I have estimated I_u from the annual labor force surveys conducted in each country that ask individuals how many weeks they were unemployed and how many spells of unemployment they experienced over the previous year.[3] I_u can be computed from

---

[1] Since the United States and Sweden were polar cases in Flanagan's study, I omitted analysis of Great Britain, the intermediate case.

[2] A referee has pointed out that Flanagan's actual estimate of I_u for the United States appears to be biased downward relative to other estimates from the monthly surveys. He estimates new entrants to unemployment each week at about 470,000 in the United States, p. 121, as compared with the Kaitz (1972) estimate of 550,000 to 750,000 for the same period. This means that Flanagan's estimate of average duration for the United States is too high.

[3] In the United States, the monthly surveys are the

$$I_u = \frac{N \times S}{52\, L} \tag{2}$$

where N is the number of individuals experiencing unemployment during the year, S is the average number of spells per person, and L is the average labor force. Although the annual surveys contain some biases from retrospective reporting (see Morgenstern and the author), they are the only source of data for the experience of workers over an entire year.[4]

In both countries, failure to look for work for less than three weeks is not considered an interruption of an unemployment spell, although those weeks are not counted in the computation of average duration. Thus, we would expect our estimate of I_u to be somewhat less than Flanagan's, with the greatest discrepancy for women and young people.

The second component of the unemployment rate is D_u, the average length of the unemployment spell. In addition to the data problems I have discussed, Flanagan uses a definitionally incorrect measure of D_u that is biased in a predictable way. To test the hypothesis that D_u does not vary between countries, Flanagan uses the rate of long duration unemployment, that is, the percent of the labor force unemployed fifteen weeks or more. This measure of D_u tells us nothing about the average duration per spell when there are differences in unemployment flows between the two countries. In fact, if the high duration unemployment rates are the same for two countries, then the one with a higher flow into long duration unemployment will have shorter durations per spell.[5] Although Flanagan purports to determine whether the "average time spent between jobs" (p. 127) varies between countries, his conclusion that international differences in duration are not significant (based on a comparision of long duration unemployment rates) is not accurate when a correct measure of D_u is used.

There are some problems in measuring D_u. The duration concept required by (1) is the average length of the completed unemployment spell, not the length of time the unemployed have been unemployed.[6] Since the duration measured in the monthly surveys is average age rather than life expectancy, there may be some bias in using these data for D_u. Consequently, I computed D_u from the annual surveys for the United States.[7] Since the annual surveys were only available for three years in Sweden, I used the monthly surveys to estimate D_u after ascertaining that there was very little difference between the two measures in the overlapping years.[8]

Current Population Survey (*CPS*) and the annual survey is the *Work Experience Survey* (*WES*). In Sweden, the monthly survey is the *Arbetskraftsundersökningen* (*AKU*) and the annual survey, compiled by the Swedish Labor Market Board (*AMS*) is generally referred to as the *AMS* survey. Since the *AMS* survey is only available for three years, we extrapolated from the Swedish monthly surveys on the basis of relationships found for those three years. This will be discussed below.

[4] There are two major types of problems associated with the annual surveys. The first are retrospective reporting biases. Morgenstern and the author have shown these biases are insignificant for central-age white males and most important for women, blacks, and teenagers. This does not affect our criticism of Flanagan's results since our conclusion holds for central-age white males as well as for other demographic groups. A second type of problem with the annual surveys is related to some technical points such as the truncation of unemployment spells at the beginning and end of the year. These problems, however, should not bias international comparisons when the surveys being compared deal with these technicalities similarly.

[5] Long duration unemployment does not measure the average duration of all unemployment spells, either. But for Sweden and the United States, differences in D_u are reflected in corresponding differences in long duration unemployment.

[6] The required measure of duration is analogous to life expectancy while the monthly surveys measure average age of unemployment. Unlike chronological age where life expectancy declines with age, average age of unemployment may be greater than life expectancy to the extent that the expected length of the unemployment spell increases with the survival rate. For a discussion, see Suits and Morgenstern.

[7] Although there is a slight downward bias associated with those individuals who were unemployed at the end of the year (and had not completed their last spell of unemployment) this measure is closer to the life expectancy concept required in equation (1) than the monthly survey data.

[8] This suggests that in Sweden the expected length of the unemployment spell does not vary very much with the survival rate.

TABLE 1—THE WEEKLY FLOW INTO NEW UNEMPLOYMENT (I_u) AND AVERAGE DURATION PER SPELL (D_u) (IN WEEKS) IN SWEDEN AND THE UNITED STATES

Sweden: D_u and UN_A, Statistika Centralbyrån, *Arbetskraftsundersökningen* (*AKU*); I_u computed from $UN_A = I_u D_u$.

United States: D_u and I_u computed from data from Bureau of Labor Statistics, *Work Experience Survey of the Population* (*WES*). Based on computed survival rates of unemployment, for men the point estimate for those in the category "27 or more weeks of unemployment" is 33 weeks and for women it is 44. UN_P computed from $UN_P = I_u D_u$; UN_A, Bureau of Labor Statistics, *Current Population Survey* (*CPS*).

[a] (Whites only.) The data for 1964 and 1965 include 14- and 15-year-olds who are excluded thereafter.

III. Empirical Evidence

Table 1 shows D_u and I_u for Sweden and the United States for those years for which data are available. For the United States, both D_u and I_u are computed from the retrospective survey,[9] UN_P is the unemployment rate obtained from equation (1) and UN_A is the official (*CPS*) unemployment rate. The difference between UN_A and UN_P is the bias from retrospective reporting.

In Sweden, on the other hand, the retrospective surveys were available for only three years. Furthermore, they tended to overstate the actual amount of unemployment. Most likely this was due to the somewhat ambiguous nature of the unemployment concept in Sweden where the unemployed are often provided temporary, relief-type, government jobs that in retrospect are recalled as "unemployment." Nevertheless, the estimate of duration from the annual survey was sufficiently close to that in the monthly surveys (an average of 13.85 weeks

---

[9] The relation between my estimate of I_u and Flanagan's is interesting. For 1970, the only year for which he provides data, his I_u for white males is .42 (relative to my .49) and for white females, .70 (relative to my .48). This suggests that the basic problem with his measure is associated with the short-run changes in labor market status that characterize female workers. This is consistent with our finding in an earlier paper that the greatest discrepancy between the monthly and annual unemployment surveys is for female workers. Possible explanations are discussed in the paper of the author and Morgenstern.

TABLE 2—PERCENT DISTRIBUTION OF DURATION OF UNEMPLOYMENT IN SWEDEN (1970) AND THE UNITED STATES (1969)

Sweden	less than 5 weeks	5–8	9–12	13–26	27+	
Percent	49.9	17.6	8.8	13.0	10.7	
Cumulative percent	49.9	67.5	76.3	89.3	100.0	
United States[a]	less than 5 weeks	5–6	7–10	11–14	15–26	27+
Percent	57.5	9.3	12.9	7.1	8.5	4.7

compared with 12.83 weeks in the monthly surveys) that I felt justified in using the duration estimates from the monthly surveys for D_u.[10] If anything, the monthly surveys may understate D_u somewhat. I computed I_u implicitly from the official unemployment rate, using equation (1).

Flanagan contends that differences in the *U.S.* and Swedish unemployment rates are due entirely to differences in I_u. But these data show that although Swedish unemployment rates are about one-half those in the United States, Swedes experience significantly longer average spells of unemployment than Americans. Swedish males have unemployment spells that are nearly twice as long as white males in the United States.[11] It appears that Flanagan underestimated I_u for the United States relative to Sweden. Furthermore, because he never estimated average duration per spell as required by equation (1), he failed to observe the sizeable differences in D_u between the two countries.

Because of Flanagan's interest in long-term unemployment, I also examined the distribution of duration among the unemployed. Table 2 shows the percent distribution of duration of unemployment in Sweden and the United States for the most recent high employment year in each country. Over 10 percent of the Swedish unemployment was over twelve weeks in duration while less than 5 percent of the *U.S.* unemployment was for more than fourteen weeks. It appears that Flanagan found no difference in the long duration unemployment rates (U_D) for the two countries because U_D contains an element of turnover which is higher for the United States. That is, since the United States has higher unemployment rates, long duration unemployment represents a smaller proportion of total unemployment. In fact, Flanagan himself estimates that if both Sweden and the United States had the same unemployment rate, the long duration unemployment rate would be higher in Sweden. Because his sample contained earlier years than mine, however, there may have actually been somewhat less intercountry variation in D_u than I found since there is evidence of a secular upward trend in duration for Sweden but not for the United States.[12]

IV. Implications

Economists are concerned about unemployment for a number of reasons. Flanagan seems to view the problem as one of labor market maladjustment; that is, a failure to achieve equilibrium. Others are concerned with the welfare of the individuals experiencing unemployment and infer from international differences in unemployment rates that workers are worse off in the United States. In addition, there is the concern for the foregone output that is seen as the opportunity cost of price stability. Thus, the opportunity cost of stopping inflation is often considered to be higher in the United States than in Western Europe.

---

[10] The monthly survey estimates were used even where the annual survey estimates were available for consistency.

[11] Blacks were deliberately excluded from the *U.S.* data so that our results could not be attributable to demographic factors.

[12] There seems to be an error in Flanagan's Table 5 in which the coefficient on the time trend in the Swedish equation is insignificant, contrary to the textual exposition.

Our finding that Swedish workers become unemployed less often than Americans but take longer to find jobs once they become unemployed has important implications for all these concerns. First, if labor market efficiency is related to the *speed* with which job seekers are matched with vacancies, the *U.S.* labor market is more efficient in this respect than the Swedish. An argument could be made that efficiency is not reflected in few job changes but in the ease with which job changes can be made. Thus, Flanagan's contention that the *U.S.* labor market exhibits the most incomplete adjustment of supply and demand does not seem to be the case.

With respect to the welfare of the worker who experiences unemployment, the analysis is complicated by an inability to distinguish between voluntary and involuntary unemployment. Within a search theoretic model, high I_u may reflect more efficient (and hence beneficial) sampling of the job market or it may imply excessive involuntary separation rates. Robert Hall has suggested on the basis of demographic analysis that the major unemployment problem in the United States is not long periods of chronic unemployment but frequent job changes and unemployed search by individuals who are dissatisfied with their jobs or cannot advance their careers. Blacks, unskilled workers, and other groups in lower labor market strata flow more frequently into unemployment than central-age white males. This interpretation suggests that the question of worker welfare must be addressed in the context of employment experience as well as the unemployment experience.

Low I_u is not necessarily indicative of more efficient labor markets or higher levels of worker satisfaction when duration of unemployment is expected to be long. I have argued in another connection (with Bo Södersten) that the longer durations of unemployment in Sweden represent a greater expected search cost for unemployed individuals. This may help to explain why I_u is so low. Swedish workers may be more reluctant than Americans to change jobs (or at least to undergo unemployed search) and will resist threatened layoffs more strongly. If workers become locked into unsatisfactory jobs because of labor market inefficiency—that is, the failure to match seekers with jobs in a reasonable period of time—this *captive worker effect* may understate the actual welfare loss associated with a given unemployment rate. Thus, although Swedish workers have lower unemployment rates they are not necessarily better off than American workers. In fact, Flanagan observes that the relatively high I_u in the United States may imply that the cost of search is sufficiently low that a larger fraction of the labor force finds unemployed search rational. I argue that this is indeed likely to be the case relative to Sweden.

Other findings of the Flanagan study lend support to the hypothesized captive worker effect. He found, for instance, that there is a strong inverse relationship between the separation rate and the unemployment rate in Sweden while no such relation exists for the United States. This implies that in slack labor markets Swedish workers remain in their jobs or drop out of the labor force, while this is not the case in the United States.[13]

Flanagan notes that emphasis in *U.S.* labor market policy has been on reducing the length of the unemployment spell. In Sweden, on the other hand, attempts to reduce unemployment have focused on reducing the number of persons flowing into unemployment. These policy preferences are undoubtedly reflected in the components of unemployment experience in the two countries. But this does not imply that the captive worker effect is not operative in Sweden. In fact, it may be a manifestation of the effect. Workers are prevented from experiencing unemployment by being placed in a state program that provides low-status, low-paying, relief-type jobs. The effect of this policy is to lower the unemployment rate, but the welfare implications are far from clear.

---

[13] This is consistent with Flanagan's finding, p. 127, that labor force elasticity is higher in Sweden than in the United States.

Analysis of the demographic profile of unemployment flows in Sweden provides more evidence of the captive worker effect. In Figure 1, D_u and I_u are plotted by age.

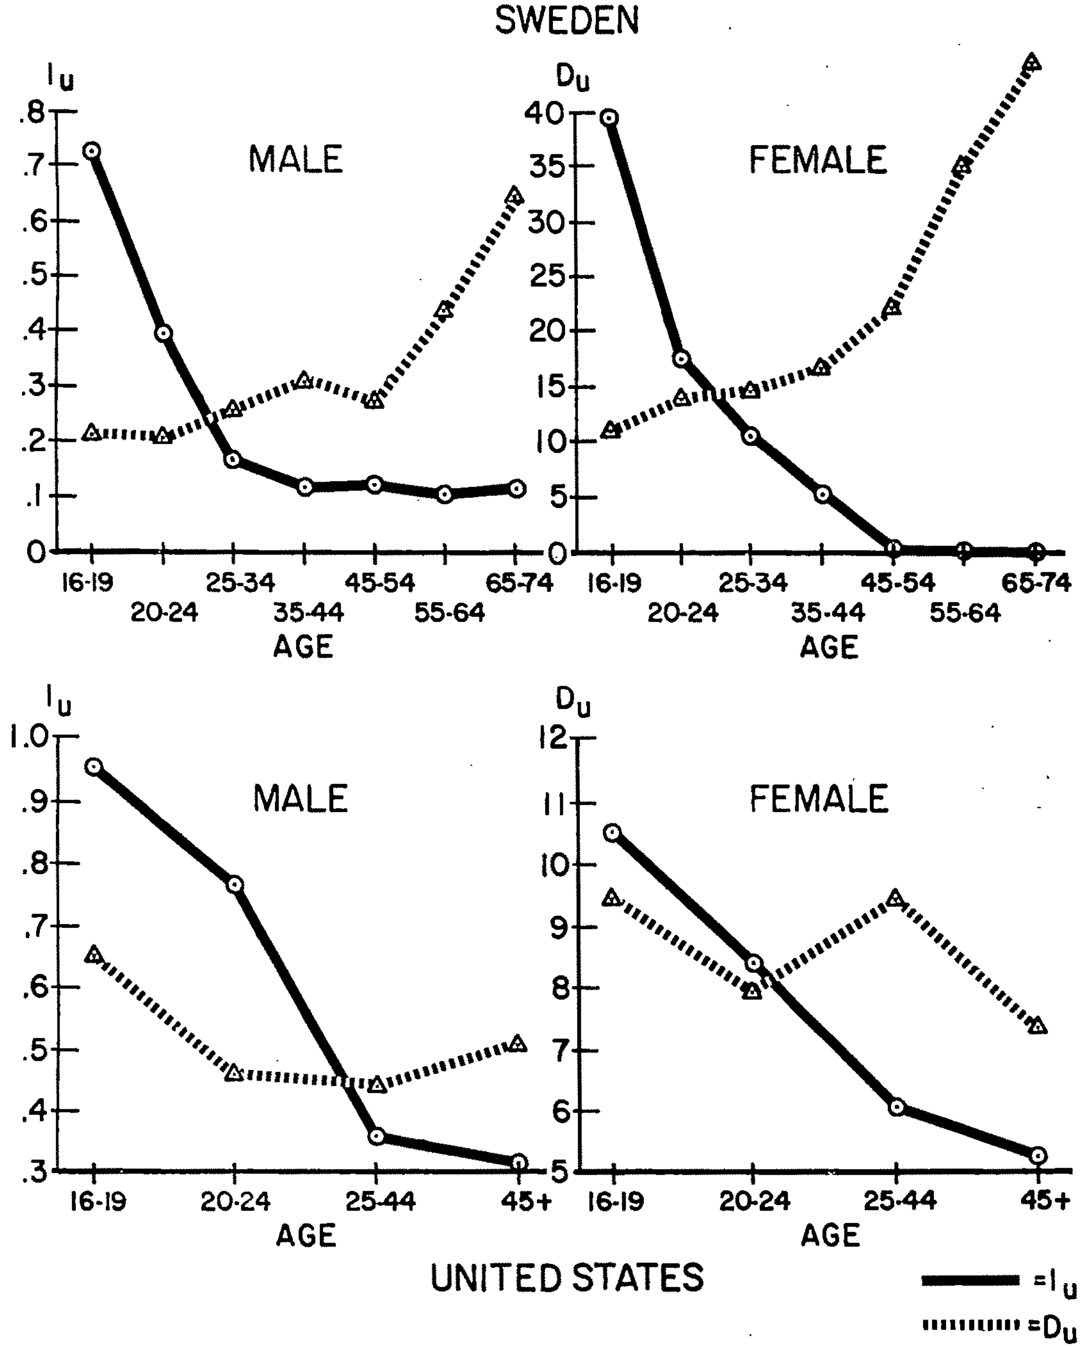

FIGURE 1

For Sweden, those age groups with long average durations of unemployment have much lower flows into new unemployment than workers who have less trouble finding jobs.[14] In the United States, on the other hand, there is no clear inverse relationship between D_u and I_u across age groups, suggesting that since expected duration is relatively short for all groups, it has less effect on workers' willingness to undergo unemployed job search. In the United States, variations in D_u and I_u seem to be more closely related to sociological factors than to labor market efficiency. (For a discussion see the author and Morgenstern.)

Flanagan considers the possibility that in tight labor markets a decline in D_u might induce a greater than proportional increase in I_u, causing the unemployment rate to rise. Using only the American data, he concludes that this type of behavior is unlikely. However, in Sweden, to the extent that workers have historically been discouraged from unemployed job search because of the expectation of a long spell of unemployment, such behavior is more likely to occur. In 1971, for instance, the unemployment rate for men nearly doubled, although the average duration actually declined. In such a case, the interpretation of the unemployment rate as a measure of labor market tightness is questionable. In the high unemployment year it took less time to find a job than in the "tighter" labor market of 1970. Although unemployment rates in Sweden over the period 1966–70 remained relatively stable, there was a tendency for duration of unemployment to rise with a concomitant decline in mobility. This suggests that Swedish workers may have experienced a welfare loss over the period that was not apparent from the raw unemployment data. The sizeable jump in the unemployment rate in 1971 and 1972 may represent a more apparent fruition of a structural problem hidden in the captive worker effect rather than an overall slackening of the labor market.

My suggestion that the welfare loss associated with unemployment might be partly related to the employment experience also has implications for the Keynesian concern with unemployment in terms of foregone output. Search theorists argue that unemployment may be productive if unemployed search leads to job changes that increase worker productivity. The captive worker effect may prevent such productivity increases. On the other hand, frequent job changes and flows into unemployment such as characterize the American economy may also be unproductive, particularly where on-the-job training is not transferable. However, there clearly is not a one-to-one correspondence between the unemployment rate and foregone output. That is, just because the *U.S.* unemployment rate is twice as high as in Sweden, this does not mean there is a greater waste of labor potential.

V. Policy Considerations

Our results support Flanagan's view that the way in which the unemployed experience their unemployment varies markedly between Sweden and the United States. In the United States the problem is not finding a job, but keeping the one presently held. The reverse holds in Sweden. In both cases, the welfare effects may be more closely related to the employment experience rather than the unemployment experience. Increased job satisfaction may cause a reduction in job changes and the flow into unemployment (I_u) in the United States. In Sweden, an increase in unemployment need not be viewed with alarm if duration is falling and more workers are moving to better jobs.

The most important conclusion to be drawn is that the unemployment rate is an imperfect measure of the welfare loss associated with unemployment, and that it is not necessarily indicative of the degree of structural maladjustment in the labor market. This is true not only when making international comparisons, but also when evaluating substrata within a national labor market. The notion that there is some full employment rate below which aggregate demand remedies are ineffective is also questionable, since the same unemployment rate may be associated with different patterns of unemployment flows. Although the Keynesian legacy has accustomed us to view the unemployment rate as the appropriate policy target, it does not recognize important variations in labor market flows that are the key to effective labor market policy.

---

[14] The same inverse relationship between D_u and I_u is evident in the regional data for Sweden. See *Årsarbetslöshetens struktur 1970, AMS*. The relationship is not as systematic in the *U.S.* regional data.

The U.S. Phillips Curve and International Unemployment Rate Differentials: Reply

By ROBERT J. FLANAGAN*

The opening paragraphs of the comment by Nancy Barrett promise far more disagreement than the rest of the paper achieves. It may minimize reader confusion if the concepts at issue are briefly reviewed before evaluating the specifics of Barrett's comment. In my paper I advanced the definition

$$U \equiv I_u \cdot D_u \tag{1}$$

as a more useful frame of reference for organizing discussions of unemployment than alternative decompositions. ($I_u = I/L$ is the proportion of the labor force becoming unemployed each week and D_u is the average duration of unemployment.) There is no disagreement between us on that point. Instead, the substantive analysis in Barrett's comment raises two conceptual issues: (a) whether published labor force survey data generally correspond to the definitions of U, I_v, and D_u; and (b) the validity of strict applications of steady-state equilibrium relationship (1) in a decidedly disequilibrium world. I shall briefly discuss each of these issues and then note their implications for the claims made in the comment.

Labor force survey data on unemployment by duration do not generally correspond to the completed duration of unemployment concept implicit in equation (1). Staying with the steady-state world for the moment, I individuals become unemployed every week as a result of quit, layoff, and labor force entry behavior. Some fraction $(1-p)$ of these individuals will complete their spell of unemployment by accepting employment or withdrawing from the labor force during their first week of unemployment, and pI $(0<p<1)$ of the cohort go on to experience a second week of unemployment. If the continuation rate p remains constant as a given weekly cohort of the unemployed ages, p^2I will experience a third week of unemployment, p^3I a fourth week, and so on. Under these assumptions it can be shown that the average duration of completed unemployment is

$$D_u = \frac{1}{1-p} \tag{2}$$

Thus, under these assumptions, Barrett's comment that D_u is higher in Sweden implies that the unemployment continuation rate p is higher in Sweden than in the United States.

If the continuation rate is constant over a spell of unemployment, the distribution of unemployment by duration reported in labor force surveys should be the same as the distribution of completed duration. However, in an important article, Hyman Kaitz demonstrated that if the continuation rate rises with the duration of a spell of unemployment, the labor force survey data will overstate the completed duration of unemployment (while a declining continuation rate will have the opposite effect). Much of the earlier discussion in the Barrett comment revolves around the argument that the gap between completed duration and reported duration in the survey data is greater in the United States than Sweden, so that the difference in I_u between the countries was understated. This reduces to an assertion that unemployment continuation rates rise more rapidly in Sweden than in the United States.

The repeated reapplication of equation (1) in Barrett's comment may lead some readers to overlook the fact that the focus of my study was a problem of disequilibrium behavior—labor market factors contributing to international differences in Phillips curves. As such, most of the empirical analysis of that paper emphasized disequilibrium (cyclical) behavior of the incidence of unemployment, separation rates, and long duration unemployment. This raises questions of the applicability of the steady-state equilibrium relation (1) in labor markets which are subject to cyclical shocks. The question may be stated as follows: During a cyclical contraction (expansion) will data on I_u and D_u yield accurate measures (predictions) of U when substituted into equilibrium relation (1) (as, for example, Barrett does in computations in Table 1)?

---

* Assistant professor of labor economics, Graduate School of Business, University of Chicago.

Consider two changes which would generate increased unemployment during a recession. In scenario number 1, I_u, the weekly flow of unemployment remains unchanged, but the probability of incurring another week of unemployment p rises. Suppose initially that $I_u=.01$ per week and $p=.50$, then by equations (1) and (2), in equilibrium completed duration $D_u=2$ weeks and $U=.02$. Now suppose that with weakened demand, p rises to .75. With $I_u=.01$, we now have $D_u=4$ and $U=.04$ *in equilibrium*. However, this equilibrium is not achieved until the full effects of the increase in p work their way through the system many weeks later. During the period of adjustment, however, actual unemployment is considerably below predicted unemployment because the number of unemployed in each duration category is dominated for a while by the old (lower) continuation rate. In scenario number 2, the recession is characterized by a rise in the weekly incidence (say $I_u=.02$) but the continuation rate remains unchanged (say $p=.5$). Originally $U=.02$. With $I_u=.02$, the new equilibrium unemployment rate will be $U=.04$. In the first week, however, there is only one cohort of $I_u=.02$ (the most recent cohort) searching for a job so that the actual unemployment rate is approximately .03 rather than .04, a rate that will not be reached for several weeks.

Both of these examples carry the same message: during a period in which I_u or p is increasing, the equilibrium relation (1) will *overstate* the actual amount of unemployment in the economy. In an expansion, the converse is true: the equilibrium relation will *understate* the true amount of unemployment.

With the foregoing as background, I turn to an evaluation of Barrett's comment. There appear to be three issues of substance which I shall discuss in turn: 1) the appropriate empirical definition of I_u; 2) my analysis of the duration of unemployment; and 3) the welfare implications of a given pattern of empirical results on unemployment.

In her analysis of I_u, Barrett argues that the difference in I_u between the United States and Sweden is even greater than the results of my article indicate. After reviewing Barrett's empirical analysis along with information from other sources, I find this congenial possibility resistable. On the issue of the appropriate empirical definition of I_u, Barrett mistakenly assumes I use data from monthly surveys to measure I_u and thus pick up some technical involvement in and out of the labor force. In fact, the Swedish I_u statistic was estimated from annual data and is defined as the annual average number of people unemployed one week or less as a percent of the labor force. In any event, this should not be a major source of difference, since the spells data, which she favors, should include short spells as well.

The use of spells data will circumvent the "bunching" problem, but Barrett's analysis is flawed in two important respects. First, after arguing the merits of the unemployment spells data to motivate her equation (2), she does not use spells data for her computations of the Swedish I_u in Table 1. Instead, data on U and D_u are used to compute I_u using the steady-state equilibrium relation (1). As demonstrated above, this application of equilibrium concepts to a disequilibrium world yields biased results.

The second problem arises from Barrett's application of unemployment spells data in the *U.S.* computations in Table 1. The use of these data requires applying an arbitrary judgment when the number of spells is high. In the source cited by Barrett, *U.S.* data on unemployment spells is truncated at the category 3+ spells. To develop an estimate of S, the average spells per person in Barrett's equation (2), one must make an assumption about the distribution of actual spells across people in the 3+ category. This ***assumption is crucial*** to the magnitude of the difference between the I_u measured by the reported duration of survey respondents on the one hand, and by reported spells on the other, and this alleged difference is at the core of Barrett's argument about the relative size of I_u and D_u. Yet the text of the comment offers no statement of the assumption used and why it is justified. If, for example, Barrett simply applied three or four spells (or some similar constant to all people in the 3+ category, then the differences between her numbers and those reported in my article would be greatest for those groups experiencing the most frequent labor force turnover. This is in fact what she reports in footnote 9, but to the extent that it is an artifact of a spells assumption this difference is not real. Until the nature of the arbitrary assumption regarding *U.S.* spells is clarified and until spells data are actually used in the Swedish computations, the magnitude of the differences reported by Barrett must be regarded as suspect.

The second part of Barrett's comment concerns the duration of unemployment. There are two important reasons why the average duration of unemployment is not analyzed directly in my article. First, D_u is an extremely ambiguous dependent variable. Theories of optimal search behavior often yield implications for this statistic, but these are best tested with microeconomic data. On the other hand, D_u may also be sensitive to structural barriers in labor markets, and the use of long duration unemployment data to examine this possibility is conceptually preferable to the use of average duration data which may be influenced by other forces. Second, when dealing with problems of labor market disequilibrium, equation (1) will not hold exactly, and one is not "required" to use D_u. Indeed, it seems more important to examine some hypotheses concerning influences on D_u describing the level of the statistic.

Barrett's discussion of this issue reflects at best a careless reading of the original article. For example, Barrett makes the remarkable statement: "To test the hypothesis that D_u does not vary between countries, Flanagan uses the rate of long duration unemployment, that is, the percent of the labor force unemployed fifteen weeks or more." No such hypothesis was offered, and the analysis of long duration unemployment rates was made for another purpose which is quite explicit in the original paper. Later, Barrett states ". . . his conclusion that international differences in duration are not significant . . ." (see p. 215) and still later "Flanagan contends that differences in the *U.S.* and Swedish unemployment rates are due entirely to differences in I_u" (p. 217). I drew no such conclusion in the paper. I did conclude that my analysis did not indicate relatively severe immobilities in the United States (which would have been reflected in part in a high average duration of unemployment) but did indicate ". . . a relatively high rate of separations and labor force entry along with the associated unemployment" (p. 130). This conclusion is in no way changed by Barrett's numbers.

A final distortion is found in the sentence, "It appears that Flanagan *found no difference* in the long duration unemployment rates (U_D) for the two countries because U_D contains an element of turnover which is higher for the United States" (p. 217, emphasis added). This, too, is an extremely imaginative statement in view of the data in the first full paragraph on page 129 of my article (as well as some of the numbers on page 128, which correspond to data provided in Barrett's Table 2).

Putting these difficulties aside, is it reasonable to conclude the D_u is relatively high in Sweden? Combining labor force survey data published in Statistiska Centralbyrån with assumptions about the mean duration of unemployment within broad duration categories which should yield estimates of D_u that are biased upward, I estimate the annual average duration of unemployment for both sexes to range between about 6.5 weeks and 8.5 weeks during the late 1960's. Although the year-to-year movements in these estimates correspond to those reported in Barrett's Table 1, the level is well below the estimates she reports for each sex. Of course, the most useful concept is that of completed duration. As noted earlier, however, for average completed duration to greatly exceed average duration as reported in the surveys, the unemployment continuation rate should decline as a spell of unemployment rate wears on. If this is the missing fact that reconciles my estimates with Barrett's, it is interesting to note that 1) it is the opposite of the behavior of unemployment continuation rates in the United States (see Kaitz), and 2) it does not accord well with Barrett's captive worker story.

The final issue regards the welfare implications of unemployment rate differentials. If Barrett feels that I arrived at strong conclusions regarding the welfare implications of *U.S.* or Swedish unemployment rates as a result of my analysis, she has seriously misread my article. Indeed, the final paragraphs of the article (p. 130) display a definite agnosticism concerning both the welfare implications of international unemployment rate differentials given the knowledge then available on the reasons for relatively high *U.S.* turnover and unemployment flows.

Barrett is considerably less cautious in a section that is distinguished by a relatively high ratio of speculation to evidence.[1] Most of Barrett's comments flow from the notion that the speed with which a worker finds a job may be an index of labor market efficiency, the observation of a relatively high D_u in Sweden, and an asserted captive worker effect. One important error in Barrett's reasoning is the presumption that spells of unemployment are always completed by accepting a job. The fact that some unemployment spells are terminated by labor force withdrawal weakens the use of D_u as an index of labor market efficiency. For example, within the United States, the *Current Population Survey* data report very similar average unemployment durations for black and white males. However, in an analysis of gross flow data, George Perry has found that the probability of terminating a spell of unemployment by labor force withdrawal is greater for blacks than for whites. Is the labor market for each race equally efficient?

Retaining the racial example, it is well known that behind the similar D_u is a black-white unemployment rate ratio of two to one. This implies a relatively large flow of new unemployment for blacks. Are the markets equally efficient? Recent analyses suggest not. These indicate that the practice of wage discrimination and occupational segregation tends to raise black turnover and associated unemployment, and that the probability of incurring unemployment, conditional on turnover, is higher for blacks. Readers may at least be able to agree with Barrett that a given unemployment rate is an imperfect measure of the welfare loss of joblessness.

[1] In one instance, Barrett misreports regression results from Table 4 of my article in an effort to muster support for the "captive worker hypothesis." Contrary to Barrett's claim, the regressions reported in Table 4 show an inverse relation between the separation rate and the unemployment rate in the United States (as well as Sweden).

On The Reward System

By LIANG-SHING FAN*

The importance of the bonus structure in a public sector dominated economy has been noted by many writers. Since economic reforms in the *USSR* and many other socialist countries were initiated in the early 1960's, there have been a few studies analyzing the bonus schemes in Soviet-type economies. (See S. Gindin, Michael Ellman, Michael Keren, James A. Mirrlees, and Wayne A. Leeman.) The trend toward profit-related bonus schemes has been continuing in socialist economies, except China's industrial sector which completely dropped the bonus as a revisionist deviation.

There are two basic problems involved: one is the bonus which induces a greater effort than the normal exertion, and the other is the tautness (or slackness) of the plan that discourages (or encourages) the effort. Gindin noted the effort-inducing effect of the bonus and the fear of a potentially higher new plan target when the current plan is fulfilled or overfulfilled. His model explains the managers' and planners' conflicting interest, which is inherent in a planned economy.[1] Leeman discussed some bonus formulae in a Soviet-type economy. He noted that if the reward were given only to the fulfillment of physical output targets, managers would tend to ignore the volume, and if the reward were based on the volume, then managers would be indifferent to plans. However, he also noted that the bonus for overfulfillment induces the managers to understate their capacities. There is a conflict in the output-plan and profit-related bonus.[2] Ellman (1973) further analyzed the bonus based on the profit which reduces managers' incentive to understate the capacity. Ellman (1971) also made a detailed analysis of the institutional background of the *USSR* economy of the late 1960's that provides invaluable understanding of the Soviet reward system.

Keren's highly analytical paper emphasizes the tautness of plans and the effort-inducing bonus. Basically Keren tried to show that there exists, given a bonus, the highest permissible target, and also to show that there exists an "optimum size of bonus" which elicits the maximum exertion (effort) given the planned target.[3] Mirrlees, in a recent paper, demonstrated that when the uncertainty about agents' characteristics is ignored, a nearly optimal incentive system is "... to threaten dire punishment of the unlucky (or lazy) and give everyone else the same payment, the payment being just high enough to make sure that people are willing to offer themselves as agents despite the threatened penalties" (p. 5).

In this note, a bonus scheme which possesses some desirable characteristics is presented. It will be shown that managers operating under this reward system will have no incentive to understate or overstate their production capacity and they will strive to attain their target profits set by the planning authority.[4]

I wish to thank Leonid Hurwicz for support and encouragement. I am also grateful to an anonymous referee who provided comments for the revision of this paper but I retain sole responsibility for its content.

[1] Gindin's utility function, pp. 147–48, is

$$u = f(B, T_n, T_0) \qquad \text{where } B = g(T, X)$$

$$\frac{\partial u}{\partial B} > 0, \qquad \frac{\partial u}{\partial T_n} < 0, \qquad \frac{\partial B}{\partial X} > 0$$

where B is the bonus. X the output, T_0 the current target, and T_n, the new target, are related to the current target as $T_n = T_0 + \mathrm{t}(X - T_0)$.

[2] See Leeman, pp. 444–45.

[3] Keren's managers have utility functions $u(x, c)$ where x is effort, c is consumption, and $u_c > 0$, $u_x \leqq 0$. However, the effort is induced by bonus as $\partial x/\partial b \geqq 0$ (see Keren, p. 477).

[4] In this analysis, there is always an uncertainty about the appropriateness of the output and input prices in the transition period for the calculation of profit. An implicit assumption is that the central plan-

I. The Bonus Structure

The exertion of effort depends upon the bonus structure $B(\pi)$ and the planned target profit π_0. It is the prospect of a potentially better reward which motivates managers and workers to work harder. The bonus can be higher when the planned target is fulfilled or overfulfilled; while there will be a danger of penalty when the target profit is not attained. Thus managers can insure a high bonus when the target is set low, but the low target and substantial overfulfillment during a current period usually mean a higher target in the next period. The profit can be higher if managers can minimize the cost of production. In this section, I try to analyze properties of a bonus scheme which seems to possess certain desirable characteristics.

The difficulty encountered by the planner in setting up the planned target for an economic unit is the tremendous informational requirements,[5] for example, necessary technological data of each unit. Depending upon the accuracy of the information provided by managers and the a priori information possessed by the planning office, the planned target may be "taut" or "slack." If we can devise a bonus scheme under which managers will have all the incentive to report the maximum (normal) production capacity and the incentive to fulfill the planned target, the informational requirements can be drastically reduced and the planned target will be (nearly) optimal or "reasonable" (neither taut nor slack).[6]

Let us define the bonus-penalty structure[7] as

$$(1) \qquad B(\pi) = \alpha\pi_0 + \beta(\pi - \pi_0) \qquad \alpha, \beta > 0$$

In the case where $\alpha = 0, \beta > 0$, the economic unit has the incentive to provide the planning authority false information about its normal production capacity. Thus π_0 will be set low in order that there will be a higher probability of overfulfillment of the plan. Subsequently, the bonus will be large. However, this incentive to cheat may be counterbalanced by the danger that π_0 for the (t+1)th period will be set much higher than that of the t-th period. In order to reduce the incentive to cheat on the reporting of the production capacity so that a high level of net benefit (profit) production is guaranteed, α is set high relative to β. In general $\alpha > \beta$, but it depends upon the underlying behavior with respect to risk aversion, etc.

Moreover, in order to avoid overstatement of the production capacity because of higher reward due to $\alpha > \beta$, we have to penalize the underfulfillment of the planned production. These measures are structured in such a way that the incentive to understate and the incentive to overstate the normal production capacity for the norm setting (π_0) of the planning authority is reduced.

In general we may write the reward system as[8]

$$(2) \qquad B = \alpha\{\pi_0 + [1 + \epsilon \operatorname{sign}(\pi_0 - \pi)] \cdot [\pi - \pi_0]\}$$

where $\epsilon > 0$ and ϵ will be preceded by the sign ($\pm$) depending upon $\pi_0 \gtrless \pi$. We may write this more specifically

(2a) In case of $\pi = \pi_0$, the bonus $B = \alpha\pi_0$ (target fulfillment)

(2b) In case of $\pi > \pi_0$, $B = \alpha[\pi_0 + (1 - \epsilon) \cdot (\pi - \pi_0)]$ (overfulfillment)

(2c) In case of $\pi < \pi_0$, $B = \alpha[\pi_0 + (1 + \epsilon) \cdot (\pi - \pi_0)]$ (underfulfillment)

The question to ask is whether (2) can eliminate the incentive to cheat on the information necessary in setting the target π_0 and whether the incentive to fulfill the target is preserved.

---

ning authority has approximated a proper set of socially desirable prices. This point was noted by E. G. Liberman, and others. I am grateful to the referee for clarifying this point.

[5] See Leonid Hurwicz (1969) for the informational efficiency of processes.

[6] Keren asserts that the optimum target is reached when given the bonus, the effort cannot be increased by raising the target, i.e., $\partial x/\partial Q^* = 0$ where Q^* is the target.

[7] It is similar to the one presented in Ellman (1973, p. 652).

[8] This formulation was suggested by Hurwicz.

A. *Deterministic Case*

If π^* is the maximum capacity of the ith unit and it is truthfully reported, then fulfillment of the plan will mean

$$(3)\qquad B = \alpha\pi^*$$

If the ith unit understates the production capacity by δ ($\delta > 0$), the result will be $\pi_0 = \pi^* - \delta$.

If the ith unit produces $\pi = \pi_0 = \pi^* - \delta$, the bonus will be

$$(4)\qquad B = \alpha[\pi^* - \delta] < \alpha\pi^*$$

If the ith unit produces at the maximum capacity π^*,

$$(5)\qquad \begin{aligned} B &= \alpha[\pi^* - \delta] + \alpha[(1-\epsilon)(\pi^* - \pi^* + \delta)] \\ &= \alpha\pi^* - \alpha\delta + \alpha\delta - (\alpha\ \delta\ \epsilon) < \alpha\pi^* \end{aligned}$$

If the ith unit produces less than the $\pi_0 = \pi^* - \delta$, say by γ,

$$(6)\qquad \begin{aligned} B &= \alpha[\pi^* - \delta] + \alpha[(1+\epsilon)(\pi^* - \delta \\ &\qquad - \gamma - \pi^* + \delta)] \\ &= \alpha\pi^* - \alpha\delta - \alpha\gamma - \alpha\epsilon\gamma \\ &= \alpha\pi^* - \alpha[\delta + (1+\epsilon)\gamma] < \alpha\pi^* \end{aligned}$$

Thus we may state that the bonus structure (2) will preserve the incentive to report and to fulfill the target (of the maximum capacity).

B. *Stochastic Case*

Suppose that π^* is the normal capacity of the ith unit and the probability is .5 that π^* is attainable, while there is a .25 probability that $\pi^* \pm \delta$ are attainable.

Then the expected value of the bonus when this norm is reported will be

$$(7)\qquad \begin{aligned} E(B) &= (1/2)\alpha\pi^* + (1/4)\alpha[\pi^* + (1-\epsilon) \\ &\qquad \cdot(\pi^* + \delta - \pi^*)] \\ &\qquad + (1/4)\alpha[\pi^* + (1+\epsilon) \\ &\qquad \cdot(\pi^* - \delta - \pi^*)] \\ &= \alpha\pi^* - (1/2)\alpha\epsilon\delta \end{aligned}$$

Case of Underreporting. If ith economic unit reported the condition so that the Planners set the norm π_0 as $\pi_0 = \pi^* - \mu > 0$, then the expected value of the bonus is

$$(8)\qquad \begin{aligned} \underline{E(B)} &= (1/2)\alpha[(\pi^* - \mu) + (1-\epsilon) \\ &\qquad \cdot\{\pi^* - (\pi^* - \mu)\}] \\ &\qquad + (1/4)\alpha[(\pi^* - \mu) + (1-\epsilon) \\ &\qquad \cdot\{\pi^* + \delta - (\pi^* - \mu)\}] \\ &\qquad + (1/4)\alpha[(\pi^* - \mu) + (1+\epsilon) \\ &\qquad \cdot\{\pi^* - \delta - (\pi^* - \mu)\}] \\ &= \alpha\pi^* - (1/2)\alpha\epsilon(\delta + \mu) \end{aligned}$$

Equations (7) and (8) will yield

$$E(B) - \underline{E(B)} = (1/2)\alpha\epsilon\mu > 0$$

Thus underreporting of the normal capacity will be bonus reducing. Thus there will be no incentive to underreport.

Case of Overreporting. Analogously, if the ith economic unit reports conditions (provides false information) so that the target is set to be $\pi_0 = \pi^* + \mu$, then the expected bonus will be

$$(9)\qquad \begin{aligned} \overline{E(B)} &= (1/2)\alpha[\pi^* + \mu + (1+\epsilon) \\ &\qquad \cdot(\pi^* - (\pi^* + \mu))] \\ &\qquad + (1/4)\alpha[\pi^* + \mu + (1-\epsilon) \\ &\qquad \cdot[\pi^* + \delta - (\pi^* + \mu)]] \\ &\qquad + (1/4)\alpha[\pi^* + \mu + (1+\epsilon) \\ &\qquad \cdot[\pi^* - \delta - (\pi^* + \mu)]] \\ &= \alpha\pi^* - (1/2)\alpha\epsilon(\mu + \delta) \end{aligned}$$

Equations (7) and (9) will yield

$$E(B) - \overline{E(B)} = (1/2)\alpha\epsilon\mu > 0$$

Thus there will be no incentive to overstate the normal production capacity. These simple illustrations indicate that the bonus structure (2) is "incentive" unbiased in the sense that individual units will have nothing to gain by under- or overreporting the normal production capacity.

II. Concluding Remarks

Ellman reported that the results of the establishment of such a reward system have not been totally satisfactory because of some uncertainties involved in the transitional period such as the appropriateness of the set of prices announced by the planning authority. Keren, p. 482, pointed out that the most important uncertainty is the delivery of inputs from other units. Liberman also reported the difficulty of the economic reform implementation because procedures of the measurement of profit are still evolving gradually. Nonetheless, the importance of the reward system has been firmly established in most of the socialistic economic systems, from Yugoslavia to the Soviet Union. However, the role of a well-devised reward system is not limited to planned economies. In any large-scale private enterprise where corporate planning is based on the information provided by numerous production units and in any public enterprise in market economies, the efficiency of production depends upon the reward system. The bonus structure (2) can be empirically tested in a given economic unit by varying the parameters α and ϵ so that a maximum effort-inducing formula can be approximated. A related fundamental issue of the existence of an incentive-compatible resource allocation mechanism was discussed in Hurwicz (1972, 1973a, b).

The Industrial Composition of U.S. Exports and Subsidiary Sales to the Canadian Market: Comment

By DALE ORR*

In his paper in the March 1972 issue of this *Review*, Thomas Horst concludes ". . . tariffs imposed by the foreign country encourage *U.S.* firms to substitute subsidiary production for exporting" (p. 43). Initially this conclusion seems unquestionable. Horst did develop the micro-economic foundations which would lead to a negative relationship between tariffs and his measure of *U.S.* penetration. His estimation of this relationship across Canada's major group manufacturing industries provided strong statistical support.

The empirical relevance of tariffs to the foreign firm's production location decision is crucial to policy makers. After several studies based on questionnaires (see Herbert Marshall, Frank Southard, and Robert Taylor; A. E. Safarian; and D. Brash), Horst's paper is the first direct econometric investigation. This alone is justification for further study. Additionally, however, some of Horst's assumptions and procedures are questionable, and more detailed data has since become available. Reexamination of this issue is thus imperative.

I first consider alternative, and I allege more reasonable, treatments of excise taxes, sample size, measurement of tariff variables, and functional form of estimating equation. It will become apparent that these modifications only slightly weaken Horst's conclusion when the model is estimated at the major group level. However, the tariff is clearly insignificant when the same model is estimated at the more disaggregated three-digit level.

I shall use Horst's notation in what follows:

$X_i \equiv$ *U.S.* exports of commodity i to Canada, divided by total Canadian sales of i

$P_i \equiv$ Sales of commodity i in Canada by *U.S.*-owned subsidiaries, divided by total Canadian sales of i

$S_i \equiv X_i + P_i$

$Z_i \equiv$ ratio of Canadian market size to *U.S.* domestic production of i

$t_i \equiv$ nominal tariff rate on imports of i

$e_i \equiv$ effective tariff rate on imports of i

I. A Reexamination of Horst's Analysis: Estimates at the Major Group Level

I first question Horst's inclusion of excise taxes within his measure of the tariff rate. These excise taxes were (unknown to Horst at the time) inappropriately included in James Melvin and Bruce Wilkinson's original measures of the tariff rate. The foreign firm would pay the tax regardless of whether it supplied the Canadian market via a Canadian subsidiary or imports by Canada. Therefore excise taxes should not be expected to explain cross-section differences in X/S. Equation 1) of Table 1 repeats Horst's basic results (p. 41) where excise taxes were included in the nominal $(1+t_1)$ and effective $(1+e_1)$ tariff rates for the beverage and tobacco industries. When these excise taxes are subtracted out, neither tariff variable is as negatively associated to the import-total penetration ratio (X/S), (see equation 2)).

Next I examine the results of dropping and combining industries for Horst's sample of seventeen major group industries, rather than the complete set of twenty. I take data on Canada's imports from the United States, production by *U.S.* controlled corporations in Canada, and tariff rates for each of the seventy-one well-defined three-digit manufacturing industries.[1] These three-digit in-

TABLE 1—THE IMPACT OF TARIFFS ON THE METHOD OF *U.S.* PENETRATION: ESTIMATES OVER THE MAJOR GROUP INDUSTRIES

Equations	Imports/total penetration variable	Constant	Tariff Variable	Canada/*U.S.* cost of production advantage	R^2	N
1)	$\ln (X/S)_H$	$-.23$	$-2.45 \ln (1+t_1)^c$	$-12.6\ Z^c$	.696	17
	$\ln (X/S)_H$	$-.38$	$-1.20 \ln (1+e_1)^c$	$-11.3\ Z^c$	.711	17
2)	$\ln (X/S)_{HI}$	.32	$-5.28 \ln (1+t_2)^b$	$-16.1\ Z^c$	.609	17
	$\ln (X/S)_{HI}$	.39	$-3.77 \ln (1+e_2)^b$	$-15.7\ Z^c$	.636	17
3)	$\ln (X/S)$	.63	$-4.95 \ln (1+t_3)^b$	$-23.5\ Z^c$	.722	17
	$\ln (X/S)$	.68	$-3.75 \ln (1+e_3)^c$	$-22.3\ Z^c$	.753	17
4)	$\ln (X/S)$	.37	$-5.32 \ln (1+t_4)^a$	$-21.02\ Z^c$	.548	20
	$\ln (X/S)$	.27	$-3.28 \ln (1+e_4)^b$	$-19.85\ Z^c$	.541	20
5)	X/S	1.29	$-\ .77\ \ (1+t_4)^b$	$-\ 2.59\ Z^c$	.428	20
	X/S	.96	$-\ .45\ \ (1+e_4)^b$	$-\ 2.43\ Z^c$	.427	20

[a] Significant at the .90 level, one-tail test.
[b] Significant at the .95 level, one-tail test.
[c] Significant at the .99 level, one-tail test.

dustries are then combined into their appropriate major group industries. Those major group industries that are dropped or combined by Horst are then treated likewise to give seventeen observations quite comparable to Horst's. Horst's value of Z will be used in all regressions. The prime difference between my data set and Horst's is that my data on major group industries are based only on their well-defined three-digit components. Horst's data also include the manufacturing activity in the three-digit industries identified as "other" or "miscellaneous." These usually account for only about 15 percent of total Canadian manufacturing. It is not surprising then that our variables are highly correlated to their counterpart in Horst's data. Horst's and my measures of X/S $(1+t, 1+e)$ are correlated .85 (.98, .98). Comparison of equations 2) and 3) indicates that my data set yields results quite consistent with Horst's.

Horst's equations are estimated over a sample of seventeen, rather than the complete set of twenty major group industries. He dropped the food industry and combined the textile, clothing and knitting mills industries, partly because of difficulties with the import data. As a measure of the major group tariff he weighted the tariffs of the three-digit components by *total* imports by Canada. Since the dependent variable is based on *U.S.* imports, the tariff rates should more appropriately be weighted by imports only from the United States (if, indeed, imports is the relevant weighting factor). Weighting the three-digit tariffs by the data on *U.S.* imports not only permits construction of more appropriate tariff data at the major group level, but permits expansion of the sample to the complete set of twenty major group industries. Comparison of equation 4) with equation 3) reveals the tariff variables are still negative and significant after this change in calculation of tariff rates and sample size.

---

modity Trade Statistics, U.K. 1967. Classifications, calculations and conversion from commodity to three-digit data kindly provided by Gary Hewitt. 2) Production by *U.S.* controlled corporations in Canada (P): $X+P=S$. Unpublished data provided by CALURA. 3) Tariff rates t, e, Melvin and Wilkinson. The sample of seventy-one includes all those three-digit industries except those labelled "other" or "miscellaneous." It should be stressed that my access to unpublished data on *U.S.* control at the three-digit level was crucial to this study. These data were unavailable to anyone at the time Horst was preparing his paper.

These equations take *logs* of variables which are already percentages (i.e., X/S, $1+t$, $1+e$). Initially one might expect that the relationship between X/S and the tariff would be linear in percentage point differences. This specification would, of course, be tested by regressing X/S on $1+t$, or $1+e$. It seems this specification also appealed to Horst a priori. He writes that this "... logarithmic transformation was not specified a priori but only after the tendency of export [Canada's imports] shares to respond much more sharply to an increase in a low tariff than to an increase in a high tariff was observed" (p. 41). He did use the linear, rather than the *log* form, in examining this same problem for the United Kingdom and Common Market (see p. 43).

From the observation that the R^2 is higher in the *log* than the linear form, it is not accurate to conclude the *log* specification is more appropriate. These equations are predicting different quantities, i.e., $\ln X/S$ and X/S. To compare the performance of the *log* to the linear specification we calculate the values of $\ln X/S$ predicted by equation 4), i.e., $\ln X/S$. Then

$$\widehat{e^{\ln X/S}}=X/S$$

Correlating X/S and X/S, then squaring this total yields the R^2 of X/S implied by the *log* relationship of equation 4). This R^2 implied by the *log* relationship of equation 4) is greater than that of the linear relationship (equation 5)) for both nominal (.658>.428) and effective (.653>.427) tariff rates. This supports Horst's contention that the *log* specification, although it has less theoretical appeal, fits the set of data better than the linear specification.

Since the sample size is so small these results could be heavily influenced by several outlying observations. We note from the scatter diagram of each equation in Table 1 that the printing and publishing and machinery industries are industries with particularly high values of the dependent variable and low tariffs. These two outlying observations, therefore, can be expected to exert a strong influence towards negative estimates of the tariff coefficients. When these two observations are dropped from equation 2) based on Horst's data, the t-statistics on the tariff variables are barely significant at the .90 level.[2] Dropping these two observations from any of the equations based on our data (equations 3), 4), and 5)) leaves the tariff variables negative but insignificant.

From Table 1 we conclude that insertion of alternative assumptions only slightly weakens the significance of the tariff variable when the model is estimated over the major group industries. We proceed next to disaggregate the data and estimate this model at the three-digit level.

II. Estimates of the Model at the Three Digit Level

Disaggregating these twenty major group industries into their three-digit components provides the results of equations 1) and 2), Table 2.[3] Compare these results to any of the equations in Table 1, estimated over the major group industries. We note the tariff variables are not even negative, let alone significantly negative, determinants of the import-total penetration ratio when the same relationship is estimated at the three-digit, rather than major group level.

The negative significance of tariffs at the major group, but not three-digit level, is not due to arbitrary aggregation procedures, measurement error, or multicollinearity. The comparison of equations 3) and 4) in Table 1 indicated the tariff variables were significantly negative regardless of what import data were used as weights in the aggregation procedure. The major group data on X and S were constructed simply by summing the appropriate three-digit components. For some of the three-digit industries calculation of Z is quite difficult since there is no direct *U.S.* counterpart to the Canadian industry. However, Consumer and Corporate Affairs list direct *U.S.* counterparts for forty-seven

---

[2] The t-statistic on the nominal (effective) tariff rate falls from 2.24 to 1.45 (2.53 to 1.49). One-tail $t_{.90}$ with 12 degrees of freedom = 1.36.

[3] Three industries had to be dropped from the sample to estimate the *log* specification (equation 1)) since $X/S=0$.

TABLE 2—THE IMPACT OF TARIFFS ON *U.S.* PENETRATION: ESTIMATES OVER THE THREE-DIGIT INDUSTRIES

Equations	Imports/total penetration variable	Constant	Tariff Variable	Canada/*U.S.* cost of production variable	R^2	N

[a] See fn. b, Table 1.

of these seventy-one industries. Estimation of equation 2), Table 2 over only these industries also yielded positive but insignificant signs on the tariff variables. The difference in results between major group and three-digit levels is not due to multicollinearity between Z and the tariff variables. At each level of aggregation the correlation between Z and the tariff variables is negligible. Over the major group industries $1+t_4$, $(1+e_4)$ is highly negatively correlated to X/S, $r=-.39$ ($r=-.44$). At the three-digit level these correlations are slightly positive, $r=.07$ and .05, respectively.

Since the linear form (Table 2, equation 2)) fits the three-digit data set virtually as well as the *log* form (equation 1)), but is preferred on conceptual grounds, I will use equation 2) as the basis for further analysis. Examination of the residuals from equation 2) reveals that the largest residuals are predominantly positive residuals and they occur in industries with highest values of X/S. These values in turn can usually be traced to unusually low values of S. This heteroscedasticity, coupled with considerations of measurement error and theoretical reasons, suggests a weighted regression rather than equation 2) may be a more appropriate test of the hypothesis.[4] However, in the implied weighted regression (equation 3)) the tariff rates were still statistically insignificant. I conclude that higher tariffs discourage imports but there is no evidence that *U.S.* controlled production in Canada is substituted for these imports.

III. Conclusion

This paper reexamines the analysis and conclusions of Horst's pioneering study on the impact of tariffs on the method of *U.S.* penetration. Horst concluded that tariffs are a highly significant factor in explaining whether *U.S.* firms choose to penetrate the Canadian market by Canadian imports rather than *U.S.* controlled production in Canada. His conclusion is based on estimates across the Canadian major group manufacturing industries. The principle finding of my paper is that whether tariffs are an empirically relevant determinant of the method of *U.S.* penetration depends crucially on the level of aggregation of industries chosen for analysis. Insertion of several assumptions and procedures alternative to Horst's left his conclusion only slightly weakened as long as his model is estimated at the major group level. However, when this same model is estimated at the more disaggregated three-digit level the tariff rate is clearly insignificant.

---

[4] Since the variance of the residuals is larger for industries with small values of S this suggests heteroscedasticity is present. Measurement error, especially rounding error, would affect measured X/S relatively more seriously for small than large values of S. Also, the researcher may want industries with low values of S to carry less weight in the estimated relationship. That is, if $X=.10$, $P=.40$, $X/(X+P)=X/S=.20$; that may represent a more important and more explicit choice of of the method of *U.S.* penetration than the industry where $X=.01$, $P=.04$, $X/S=.20$. In equation 2), however, each of these industries carries equal weight in determining the overall relationship. It appears that the variance of the error term increases as $1/S^2$ (rather than $1/S$ or $(1/\sqrt{S})$). In this case the appropriate weight is S. Weighting by S, of course, deemphasizes the role of those industries with small values of S. These are the industries with the largest residuals, most subject to measurement error, and "least important." The fact that the industries with largest residuals have particularly low S indicates that some variable which could explain low *U.S.* penetration has been omitted from equation 2). We expect *U.S.* penetration to be particularly low in industries where the relevant market is local or regional. However, addition of a dummy variable for regional industries still left the tariff variables insignificantly different from 0. It is interesting to note however that when X (import intensity) was regressed on these variables each had the expected sign. This may instill some confidence in the data and estimates at the three-digit level.

Econometricians would not be surprised that the results are sensitive to the level of aggregation. For example, see Henri Theil (ch. 11) or Yehuda Grunfeld and Zvi Griliches. Reasons offered for sometimes preferring estimates at the more aggregate level are difficulty in specifying micro behavior, more measurement error at the disaggregated level, and desire to implement policy at the aggregate level. These reasons do not seem to support aggregation in this particular case. The major group industries contain such a diversity of products it seems more difficult to postulate a behavioral relationship between the average level of variable at this level. Tariff and import data are reported at the commodity level; foreign control at the three-digit level. Thus there appears no particular reason to suspect more measurement error at the three-digit than major group level. Recall that even when those industries likely most subject to measurement error were discounted, the tariff was still insignificant. Policy decisions regarding tariffs are most often taken at the commodity level. The decision regarding the optimum method of foreign penetration is, of course, taken at the firm level. For this particular issue, it therefore seems reasonable to place more confidence in the results at the more disaggregated level.

My results should not be interpreted as refuting Horst's conclusion, but rather calling it to question. The Horst paper is a pathbreaking study on a very relevant issue. Hopefully, my paper, like Horst's, will stimulate others to further investigation.

The Industrial Composition of U.S. Exports and Subsidiary Sales to the Canadian Market: Reply

By THOMAS HORST*

Dale Orr's comment offers several valuable and interesting criticisms of my paper. Rather than magnifying differences of judgment and interpretation of our findings, let me focus on the apparent failure of his three-digit industry data to confirm my findings based on two-digit industry statistics. This failure sheds some interesting light on the pitfalls of cross-industry analysis and indirectly on the broader issue of how tariffs affect foreign trade and investment patterns.

However simple and straightforward the analysis of tariffs may be at a theoretical level, trying to show their impact empirically is no easy task. Trade and investment patterns reflect much more than tariffs. The size and rate of growth of the recipient market, the transport and inventory cost of exporting, the availability of capital, labor, raw materials and support services, the size of start-up and overhead costs of a foreign subsidiary, the requirements for marketing the product locally and the competition from other producers, domestic and foreign, all impinge upon trade and investment flows. Firms' behavior is often constrained by past commitments, so that current behavior reflects not only current conditions, but past histories as well. Finally, the willingness of tariff setters to give more protection to local producers threatened by import competition can lead to a perverse statistical relationship between observed tariff and import levels. Although econometric solutions to the problems of simultaneous determination, lagged adjustment and these other problems, exist, the available data are too skimpy and flawed to permit the effective use of sophisticated methods.

Normally, when one moves from a higher to a lower level of aggregation, the statistical significance of estimated coefficients improves—if nothing else, one has more degrees of freedom. Accordingly, Orr's finding to the contrary is rather surprising, but not completely implausible. While there are several possible explanations for this result, in this particular instance the deterioration in statistical significance appears to be due partly to errors of misclassification and mismatching at the three-digit level, but mainly to the implicit difference in weights given to various industries.

Let me be more specific. The negative and statistically significant coefficient of the tariff variable using the more aggregate data is due to a few industries (machinery and publishing) where tariffs are lowest and *U.S.* exports largest and to a few industries (beverages, tobacco, and rubber) where tariffs are highest and *U.S.* exports smallest. Over the intermediate range, the relationship between tariffs and *U.S.* exports appears haphazard.

In disaggregating from the two- to the three-digit level, the five extreme industries were decomposed into only nine industries, while the twelve intermediate industries accounted for fifty-two industries in the new scheme. The disaggregation was implicitly a reweighting of the sample points, and an unfavorable one at that. While one could quibble with Orr on which level of aggregation is to be preferred a priori, the real question is not really one of choosing the optimal level of aggregation. Rather, the point is that in a crude, cross-industry analysis, the impact of tariff policy can be seen only in the extreme cases. While tariffs may make a difference over the intermediate range, their influence is difficult to disentangle from other considerations.

What then should we conclude about the role of tariffs in influencing *U.S.* exports and subsidiary sales to Canada and elsewhere? As Orr acknowledges, support for the notion that tariffs can effect a substitution of subsidiary production for exports rests on a far broader basis than our econometric investigations. But both published research and common sense indicate that the actual relationships are complex, and to the extent that my original paper oversimplified the issue, Orr's comment has set the record straight.

Black Education, Earnings, and Interregional Migration: A Comment and Some New Evidence

By CHARLES R. LINK*

In a recent article in this *Review*, Leonard Weiss and Jeffrey Williamson (hereafter referred to as W-W) examined the impact of education and several other factors on the earnings of a sample of black males. Utilizing multiple regression analysis and data from the 1967 Survey of Economic Opportunity (*SEO*) they find that . . . "Education has a strong and consistent effect on black incomes for the sample as a whole, and for each age group in the interaction equation" (p. 379). W-W's results differ from earlier studies using 1960 Census data that find practically no effect of black education on black incomes (see Giora Hanoch, Randall Weiss, Lester Thurow).

In order to test for the effects of full employment and, more importantly, parameter shifts that may have occurred during the 1960's, W-W apply Thurow's human capital function to their 1967 *SEO* data. They compare their estimates with Thurow's and conclude: "Our study also seems to show a significant shift in the earnings function for blacks during much of the past decade" (p. 382). They find that black incomes in 1967 appear to be at least as responsive to education as white incomes in 1960 with the increases appearing at all education levels. Finally, large increases in the impact of experience on earnings are found for young blacks (pp. 382–83).

This brief note presents further work which sheds light on whether the results obtained by W-W represent a long-term trend. Thurow's human capital function is reestimated utilizing 1970 Census data and the results compared with W-W and Thurow.

Thurow's human capital function takes the form

$$(1) \qquad Y = A\, Ed^{b} Ex^{c}$$

where an individual's income (Y) is dependent on his number of years of education (Ed) and experience (Ex), the shift coefficient (A), and the elasticities of income with respect to education b and experience c.[1] The shift coefficient picks up the effect of other relevant factors such as discrimination, market imperfections, and unionization, pp. 73–74.

To test the hypothesis that income elasticities vary for different ranges of education, Thurow disaggregates the continuous education variable into three continuous variables for the classes 0–8, 9–12, and more than 12 years of education. Experience is analogously divided into four continuous variables representing 0–5, 6–15, 16–35, and more than 35 years of experience. The disaggregated function is

$$(2) \qquad Y = A\, Ed_1^{b_1} \ldots Ed_3^{b_3} Ex_1^{c_1} \ldots Ex_4^{c_4}$$

Following Thurow, median income, age, and education data are taken directly from the 1970 Census for males aged eighteen to sixty-four and used to reestimate the human capital function. Experience is calculated by subtracting one's age of entry into the labor force from his present age. It is assumed that males with a high school education or less enter the labor force at age eighteen and college graduates at age twenty-two (see Thurow, pp. 75–76). Functions are estimated for six different groups: all black; all white; North white; North black; South black; and

* Assistant professor of economics, University of Delaware. This research was made possible by a General Faculty Research Grant at the University of Delaware. I would like to acknowledge the helpful comments of Ed Ratledge, George Borts, and a referee on an earlier draft of the paper. Helpful comments were also given by several of my colleagues at the University of Delaware. Of course, any errors are my sole responsibility.

[1] See Thurow, pp. 189–90, for a critique of the human capital function.

South white. The Census data provide eighty-six observations for each of the six groups.[2]

In the regression analysis the human capital function for each group is estimated in the form:

$$(3)\quad \ln Y = A + b_1 \ln Ed_1 + b_2 \ln Ed_2 + b_3 \ln Ed_3 + c_1 \ln Ex_1 + c_2 \ln Ex_2 + c_3 \ln Ex_3 + c_4 \ln Ex_4$$

where $Y = 1970$ median income, the Ed_i $(i = 1, 2, 3)$ are continuous variables indicating years of education to a maximum of 8, 12, and more than 12 years, respectively. Similarly, Ex_k $(k = 1, 2, 3, 4)$ represents 0–5, 6–15, 16–25, and more than 35 years of experience. Thurow omitted terminal education and experience variables whenever the standard errors exceeded their regression coefficients (pp. 72–76 and 187–88). In four of the six equations estimated in the present study, c_4 was less than its standard error and in the other two equations it was only slightly larger than its standard error. To enhance comparability with Thurow, Ex_4 is thus excluded from the 1970 regression equations reported in Table 1.[3]

Income elasticities for various levels of education and experience are calculated by adding b or c coefficients. The elasticities of income with respect to 0–8, 9–12, and more than 12 years of education are $b_1+b_2+b_3$, b_2+b_3, and b_3, respectively. Similarly elasticities of income with respect to 0–5, 6–15, 16–35, and more than 35 years of experience are $c_1+c_2+c_3+c_4$, $c_2+c_3+c_4$, c_3+c_4, and c_4, respectively (see Thurow, p. 187).[4] The estimated human capital functions for 1960, 1967, and 1970 are presented in Table 1 and the resulting income elasticities are shown in Table 2.[5]

Income elasticities of education for a particular education range should be interpreted as the percentage change in income arising from a one percentage point change in education. For instance, the income elasticity of education for all whites who attained 0–8 years of education in 1960 is .11. In this case a one percentage point increase in education is associated with an increase in income of .11 percent. Similar interpretations are given to the income elasticities for experience. Income elasticities are calculated for blacks and whites in the total United States, the North and the South.

W-W state that "Elasticities of income with respect to education [for blacks] have increased in *all* regions and *all* education classes" (p. 381). However, examination of the results for 1970 indicates that in absolute

---

[2] Thurow's analysis included 72 age-education categories. The increased number of observations in the 1970 data is due to the finer classifications of educational attainment. Each of the eight age groups with the exception of the youngest, has 11 educational categories (e.g., no school completed, 1–3 years, etc.) each of which has a corresponding median income figure. The youngest age group has only 9 educational categories. Thus the total number of observations is 86. In a small number of age-education categories for blacks there were not enough subjects to calculate a median income figure. Thus the number of observations is less than 86 and degrees of freedom are slightly lower in the black vs. white regressions.

[3] Exclusion of the more than 35 years of experience variable causes only minor changes in the education coefficients and virtually no changes in the income elasticities computed below.

[4] Examples of the way in which the data are coded for the regression analysis will give the reader an insight into why the elasticities are calculated as indicated above. Recall that Ed_1, Ed_2, and Ed_3 are continuous variables that indicate the number of years of education to maxima of 8, 12, and more than 12, respectively. Consider the cases of individuals with 3, 11, and 16 years of education. In the first case the coding is $Ed_1 = 3$, $Ed_2 = 3$, and $Ed_3 = 3$. The individual with 11 years is coded as $Ed_1 = 8$, $Ed_2 = 11$, and $Ed_3 = 11$. Finally our college graduate is coded as follows: $Ed_1 = 8$, $Ed_2 = 12$, and $Ed_3 = 16$. Coding the data in this fashion allows us to estimate the income elasticity associated with any particular education range as the sum of the coefficient for those who stopped at that level and the coefficient(s) associated with individuals who went on to attain higher levels of education. Inclusion of the latter coefficients allows for the effect of the first n years on the incomes of individuals who surpassed this level of education. Analogous reasoning is utilized in the coding of the Ex variables.

[5] Resulting $\bar{R}^2$s for 1960 and 1970 are higher as a result of using aggregate data. W-W use individual data. A Chow test was used to check for structural differences in the North and South human capital functions for both blacks and whites in 1970. The hypothesis of the same structure was rejected at the 1 percent level.

[a] The 1960 results are from Thurow, Table G-1, p. 188. The 1967 results are from Weiss and Williamson's Table 6, p. 380. The estimation equation is given in the text. Figures in parentheses are standard errors.
[b] The nonwhite category in 1960 included certain other races in addition to blacks.
[c] Not estimated for 1960 or 1970 (see text).

terms the black gains are not as impressive as W-W claim.[6] In seven of the nine potential comparisons, 1970 elasticities are less than those for 1967.

In relative terms, although the 1970 income elasticities for blacks in the 13 or more years of education range have indeed increased from their 1960 values in all regions of the country and are similar to those found by W-W in 1967, substantial increases have also occurred in income elasticities for whites with a college education. Consequently, blacks with 13 or more years of education have experienced only small gains relative to whites. The ratio of college white to college black elasticities in 1960 and 1970 is 1.30 and 1.22, respectively.

---

[6] The portion of the increase in black returns to education and experience between 1960 (i.e., Thurow) and 1967 (i.e., W-W) which is real and that which is statistical artifact is unclear. In other words, given the well-known fact of a skewed distribution of income, the use of individual data fitted through mean incomes to estimate the human capital function may or may not yield substantially different results than similar data which is aggregated and fit on median incomes.

TABLE 2—INCOME ELASTICITIES OF EDUCATION AND EXPERIENCE FOR MALES, BY COLOR AND REGION, 1960, 1967, AND 1970[a]

		Years of Education			Years of Experience				Shift Coefficient[c]
Sample		0–8	9–12	13+	0–5	6–15	16–35	35+[b]

Southern black	(1967)	0.19	1.66	2.22	1.51	0.78	−0.31	−3.44	—
	(1970)	0.06	0.62	1.93	0.16	0.55	−0.25		1578

[a] The 1960 figures are from Thurow, Table 5-1, p. 77. The 1967 elasticities are from Weiss and Williamson's Table 7, p. 381. The 1970 elasticities are calculated from Table 1.

[b] Not calculated for 1960 or 1970 (see text).

[c] Antilog of constant term (*A*).

The big relative gains have accrued to blacks in the 9–12 years of education category. Even here the absolute gains for blacks were modest between 1960 and 1970 but the corresponding white income elasticities dropped drastically. The South excepted, blacks in 1970 had larger elasticities than whites in the 9–12 years of education range.

With respect to primary education, all of the elasticities for blacks and whites alike fell during the decade of the 1960's. This deterioration reflects the competitive disadvantage confronting such males as a result of limited marketable skills and possibly a lack of credentials.

The 1970 data do not show the large increase in the responsiveness of income to experience for young blacks found by W-W, p. 381. The elasticities of income with respect to experience indicate, if anything, that whites have gained relative to blacks in the 1960's.

It is undoubtedly true that the tight labor market during the 1960's is partly responsible for the modest but positive relative gains received by blacks during the 1960's. W-W, p. 381, also give credit to legislation designed to eliminate discrimination. As was mentioned earlier the shift coefficient (*A*) reflects, among other factors, the impact of discrimination on earnings. Shift coefficients, derived by taking the antilog of the constant term (*A*), for the 1970 and 1960 models are shown in Table 2. In the North and for the whole United States, the shift coefficients for blacks although still smaller than the ones corresponding to whites have increased relative to those for whites. This is consistent with the hypothesis that civil rights legislation has at least to some degree enhanced the relative economic position of blacks.

In conclusion, even though investments in education and training have undoubtedly played a significant role in helping to improve the position of blacks during the past decade, the gains are not as large as earlier data indicated. It appears that policies in addition to human capital investments will be necessary if we are to bring about larger improvements in the economic position of blacks. Examples of such policies include a negative income tax, job creation programs, and the reduction of imperfections in the labor market brought about by factors such as racial discrimination.

Black Education, Earnings and Interregional Migration: Even Newer Evidence

By LEONARD WEISS AND JEFFREY G. WILLIAMSON*

The striking difference between the results reached by Charles Link, using published 1970 Census data, and ours, using the 1967 *SEO* tape, calls for some explanation. In an effort to find the source of the difference, this comment reports our results using the 1970 Census (1969 income and earnings) individual data from the public use tapes. We shall show that the source of the discrepancies lies with the form of the published Census data rather than in underlying economic relationships. Using individual data, we show that the effect of education on earnings is similar for blacks and whites in 1969, a result which confirms our assertions from the 1966 *SEO* data. We suspect that similar results would be forthcoming from the 1959 Census data. It seems likely that the low apparent return to black education found by Lester Thurow was also a statistical artifact. At the very least, we conclude that the use of grouped data for policy analysis of this sort is very suspect and that individual data should be used wherever possible.

The published census data is beset with numerous flaws. First, it presents data on income rather than earnings from work or self-employment. Income includes welfare transfers, unemployment insurance, and the like. As a result, the effect of education on income is apt to be weak at low levels of education compared with its effect on earnings. Second, the published data excludes persons with zero income. Since these include the unemployed, their exclusion tends to weaken the education-earnings relationship still further. Third, the published data include all males in the armed forces and in institutions (for example, jail). The education-earnings relationship may be biased downwards even further since income in kind is an enormous component of military pay. Each of these flaws in the published data apply to whites as well as blacks, but the distortion is likely to be more severe for blacks since they have higher dependence on transfers, higher unemployment rates, and higher participation in the armed forces.

In addition, the published Census data consist of median incomes for age-education groups, and three problems arise as a result. First, the census groups are quite broad. For example, median incomes are reported for those with 1–4 years of education, 5–7 years of education, etc., and for ages 18–19, 25–29, . . . , 36–44, etc. In contrast, the 1967 *SEO* tape and the 1970 Census public use tapes permit us to use precise age and education data. Second, the Thurow and Link studies gave each age-education cell equal weight, while our study is based on individual data effectively weighted by the number of individuals in a given cell. Third, the published cell medians do not reflect outliers very well, but they are included in our study. Obviously, a grouped data regression will always yield a higher R^2. Beyond that, it is not clear what a priori bias is introduced by grouping.

In an attempt to evaluate the effect of these differences we grouped the public use tape data following the census procedures, but utilizing alternative measures of income and alternative sample definitions. These results were then compared with those derived from individual data upon which the grouping was based. The results of these experiments appear in Table 1 for those in the North, Table 2 for those in the South, and Table 3 for the nation as a whole.

7. Weiss-Williamson results for 1966	.21	1.80	1.77	1.60	0.69	[a]	

[a] Our 1966 results included a fourth experience variable for those with 35 or more years experience. Thus, the estimated elasticity in this range is not comparable with the above regressions.

The first line in each of these tables reports Link's estimated elasticities. The second line shows the results derived from the public use tapes using the same population concept, the same income definition, and the same cell groupings as that published by the Census. Lines 1 and 2 differ very little, and the discrepancies are presumably due to sampling errors since our grouping procedure relied on a one in one-hundred sample.[1] Subsequent comparisons will be made with line 2 since all the remaining elasticity estimates in these tables are based on the public use tapes.

Line 3 reports elasticities when those with zero incomes are included. The result is to increase the impact of education on income in low education ranges for both races and in both parts of the country. Line 4 reports elasticities when we retain those with zero incomes, but we now also use cell median earnings from work or self-employment instead of income. Again the education elasticity in the 0–8 and 9–12 year ranges are consistently raised. Note also that northern blacks are more greatly affected than northern whites. Line 5 shows the results using the same procedures but excluding those in the armed forces or institutions. The results of this change are surprisingly equivocal.

Finally, line 6 shows the results for individual data using earnings of the noninstitutional population, and including those with zero incomes.[2] The shifts in the estimated elasticities when the individual data are used are often enormous. For low education ranges in particular, the elasticities increase by factors of five to ten. Our 1966 estimates based on the *SEO* tape are reproduced on line 7. The specifications for those are the same as in line 6. The differences between the 1966 (line 7) and 1969 (line 6) estimates require explanation, rather than comparisons between Link (line 1) and ourselves. Part of the explanation may be attributed to the fact that the *SEO* sample intentionally overrepresented the poor. The public use tapes do not overrepresent any group relative to its role in the population. One thing is certain—sampling errors cannot be large. There were 42,170 observations in the all black regression and 404,316 in the all white sample.[3]

---

[1] Another explanation for the slight discrepancies may be that we use whites and blacks while the Census tables used by Thurow and Link are for whites and nonwhites.

[2] Because the dependent variable is the *log* of earnings, those with zero earnings were assigned an income of $1. Those with negative earnings and those with zero education or experience were excluded from the sample. The largest group of exclusions were persons with zero experience (age 18 or in their first year out of school). Persons with earnings in excess of $50,000 were assigned the estimated mean earnings for their occupation class estimated on the assumption of a Pareto distribution (following Herman Miller).

It is not clear why the grouped data yield such drastically different results from individual data. One possible reason is that the Thurow-Link regressions are unweighted. However, a weighted regression for northern blacks cell median earnings for the noninstitutional population yielded elasticities similar to those in line 5 of Table 1 (.05, .72, and 1.73 for the three education ranges). The assignment of $1 to those with zero incomes in our individual observation regressions was, of course, arbitrary, but we feel it was conservative. If the unemployed had been assigned an income of 1 cent as Thurow did, we would expect the effect of education in the low range to be even stronger. In any event, when the black regressions were run again excluding those with zero income, a large though weakened effect for education remained. (For northern blacks the education elasticities were .16, .48, and 1.50. For southern blacks, they were .29, .64, and 1.66.) Finally, it should be emphasized that individuals with negative income are excluded from the individual regressions. This procedure was unavoidable given that the dependent variable is the *log* of earnings. Since only those with high permanent income (for example, high skill and education) can afford transitory negative income, it appears inevitable that the elasticities would be higher in the individual regressions. It also seems apparent to us that these individual elasticities are therefore more relevant for policy purposes.

An important conclusion from this exercise is that the effect of education on earnings is roughly as strong for blacks as for whites. We suspect the same was true in 1959 as well. The studies that yielded low returns for that period were based on grouped data like that used by Link. The widespread belief that education does not pay for blacks is certainly incorrect today Our results for 1969, like those we reached using 1966 data, still point to the usefulness of investments in black education in reducing interracial inequality.

[3] Use of the individual observations, of course, reduced R^2. In the all white sample, R^2 underlying the elasticities reported in line 5 is .818 while in line 6 it is .104. The t-ratios on the education variables ranged from 9 to 63 in the individual regression; they ranged from 1.6 to 5 on the grouped data.

Theory of the Firm Facing Uncertain Demand: Comment

By Robert M. Korkie*

In a recent issue of this *Review*, Hayne Leland concludes that the risk-averse quantity setting firm will produce less under uncertainty conditions than it would under certainty, a finding that is consistent with that of other authors including John Lintner (1970). This conclusion is based in part on his assumed property of the stochastic demand curve, called the principle of increasing uncertainty (*PIU*).[1] This paper suggests that the intuitively supported *PIU* (increases in expected total revenue are accompanied by increasing risk) is a special and unusual case.

In what follows I adopt one of the behavioral modes specified by Leland and make the same equilibrium assumptions. It is demonstrated that the principle of increasing uncertainty does not hold for one of the most widely employed measures of risk in the economic and financial literature.

Leland introduces uncertainty through the implicit demand relation

$$(1) \qquad f(p, q, u) = 0$$

where u is a random variable with subjectively estimated probability density $dF(u)$. Let us deviate somewhat from this approach and introduce uncertainty in the parameters of a linear demand relation (henceforth called the random coefficients model) given implicitly by

$$(2) \qquad g(p, q, \tilde{a}, \tilde{b}) = 0$$

where $\tilde{a}$ and $\tilde{b}$ have subjectively estimated two-parameter density functions.

Consider the all equity taxless firm whose single security equilibrium price is given by the Sharpe-Lintner-Mossin single period capital asset pricing model.[2] That is,

$$(3) \qquad V_t = \frac{E(\tilde{x}_t) - \lambda_t Cov(\tilde{x}_t, \tilde{M}_t)}{(1 + R_{F_t})}$$

where

$V_t \equiv$ the beginning of period t firm market value,

$\tilde{x}_t \equiv$ the cash profits paid at the end of t,

$\tilde{M}_t \equiv$ the market portfolio's end of period t wealth prior to dividend disbursements,

$R_{F_t} \equiv$ the risk free borrowing and lending rate for period t,

$\lambda_t = \dfrac{E(\tilde{R}_{M_t}) - R_{F_t}}{\sigma^2_{RMt} M_{t-1}} \equiv$ the market price per unit of risk per dollar of beginning of period t market portfolio wealth M_{t-1},

$\tilde{R}_{M_t} \equiv$ the market portfolio's rate of return for period t,

$\sigma^2_{R_{M_t}} \equiv$ the variance of the market portfolio's rate of return in period t,

$Cov \equiv$ the covariance operator.

Now let us choose as the behavioral mode a firm whose *ex ante* control is quantity produced over the single planning period. *Ex post* to the realization of the outcome of the stochastic demand curve, the firm then adjusts price p_t to clear the market of the produced and demanded quantity q_t. The quantity setting firm seeks to

$$\underset{q_t}{\text{Maximize}}\ V_t,$$

where V_t is given by (3) and $\tilde{x}_t$ is given by

$$(4) \qquad \tilde{x}_t = \tilde{p}_t q_t - c(q_t) - F_t$$

where the explicit random coefficient demand is[3]

$$(5) \qquad \tilde{p}_t = \tilde{a}_t - \tilde{b}_t q_t$$

---

* Assistant professor, Faculty of Business Administration, University of Alberta.

[1] Lintner (1970, p. 255) also invokes this property in a portion of his paper.

[2] See William Sharpe, Lintner (1965), Jan Mossin. For problems of assuming a constant risk price (λ_t), see Eugene Fama.

[3] It can be shown that the random coefficients model is equivalent to a model with a single additive heteroscedastic error term.

where $c(q_t)$ is the variable cost and F_t is the fixed cost. Total revenue is

$$(6) \qquad T\tilde{R}_t = \tilde{a}_t q_t - \tilde{b}_t q_t^2$$

and expected total revenue is

$$(7) \qquad E(T\tilde{R}_t) = E(\tilde{a}_t) q_t - E(\tilde{b}_t) q_t^2$$

for selected values of q_t. The riskiness of total revenue is obtained as

$$(8) \quad Cov\,(T\tilde{R}_t, \tilde{M}_t) = q_t\, Cov\,(\tilde{a}_t, \tilde{M}_t) - q_t^2\, Cov\,(\tilde{b}_t, \tilde{M}_t)$$

To determine if the principle of increasing uncertainty holds, let us examine the values of q_t for which $E(T\tilde{R}_t)$ and $Cov\,(T\tilde{R}_t, \tilde{M}_t)$ reach maximums. First-order conditions for a maximum of expected total revenue yield

$$(9) \qquad q_t^* = \frac{E(\tilde{a}_t)}{2E(\tilde{b}_t)}$$

which occurs where the elasticity of expected demand equals -1. Similarly, a maximum of the risk of total revenue occurs at

$$(10) \qquad q_t^{**} = \frac{Cov\,(\tilde{a}_t, \tilde{M}_t)}{2\, Cov\,(\tilde{b}_t, \tilde{M}_t)}$$

which we assume is a positive quantity. Second-order conditions for a risk maximum require that

$$(11) \qquad -Cov\,(\tilde{b}_t, \tilde{M}_t) < 0$$

which is the most challenging assumption under which *PIU* is disproved. Hence, the only condition under which $E(T\tilde{R}_t)$ and $Cov\,(T\tilde{R}_t, \tilde{M}_t)$ reach a simulatneous maximum is if

$$(12) \qquad \frac{Cov\,(\tilde{a}_t, \tilde{M}_t)}{Cov\,(\tilde{b}_t, \tilde{M}_t)} = \frac{E(\tilde{a}_t)}{E(\tilde{b}_t)}$$

Barring this specialized case, for some values of q_t, $E(T\tilde{R}_t)$ is increasing and $Cov\,(T\tilde{R}_t, \tilde{M}_t)$ is decreasing or vice versa. Therefore, the principle of increasing uncertainty is violated.[4]

Leland suggests in a footnote that if *PIU* is violated at some level of output and a given demand outcome, a continuous demand curve implies that *PIU* is violated in a small neighborhood of the point. It is possible, as seen from this comment, that the neighborhood may be very large, and in fact may be as large as the normal range of *ex ante* operation of the control variable q_t.

In a situation where total revenue is a random variable and costs are certain, it may seem paradoxical that increased expected total revenue is accompanied by a decline in riskiness. However, the notion of a proportional tradeoff between risk and return is a phenomenon of equilibrium and firms searching for an optimal level of output are not in equilibrium. Furthermore, it can be shown that in a general utility maximization model, if one does not restrict the deviations of marginal revenue and profit from their respective means to be of the same sign, then the effect of uncertainty on planned firm output is inconclusive.[5] This ambiguous result for price setting firms is reached by Leland for reasons related to uncertain costs.

Theory of the Firm Facing Uncertain Demand: Reply

By HAYNE E. LELAND*

Although complicated by extraneous elements,[1] Robert Korkie's criticism is based on the correct assertion that the linear stochastic demand curve

$$(1) \qquad p = \tilde{a} - \tilde{b}q$$

may not everywhere satisfy the principle of increasing uncertainty (*PIU*). Korkie concludes, perhaps with a modicum of exaggeration, that the *PIU* is a "special and unusual case."

I show below that many linear stochastic demand functions will satisfy the *PIU* for the range of outputs relevant to a profit oriented firm, even though these functions may not satisfy the *PIU* for outputs which firms will never consider. And I further suggest that the failure of the linear demand function to satisfy the *PIU* for some range of q is perhaps a better argument against the use of the linear form over that range than against the *PIU*—which Korkie admits has great intuitive appeal.

First, rewrite (1) in a form comparable to my original analysis:

$$(2) \qquad p = a(u) - b(u)q$$

where u is random. Recall our assumption that larger u's can be associated with higher prices (more favorable demands). Sufficient conditions for this to be satisfied for all q are

$$(3) \qquad a'(u) \geq 0, \qquad b'(u) \leq 0$$

with at least one inequality holding strictly. (Primes indicate derivatives.) Conditions (3) are necessary as well as sufficient, and therefore must always be satisfied if (2) introduces uncertainty either in a purely additive $[b'(u)=0]$ manner or in a purely multiplicative $[a'(u)=0]$ manner.

In the Appendix of my original paper, the *PIU* was shown to require that $\partial^2 TR(q, u)/\partial q \partial u$ have the same sign as $E[MR(q, u)]$, where $TR(q, u)$ and $MR(q, u)$ are total and marginal revenue, respectively. Using (2) and (3),

$$(4) \quad \partial^2 TR(q, u)/\partial q \partial u = a'(u) - 2b'(u)q > 0$$

Therefore, the linear stochastic demand curve satisfies the *PIU* for all q such that expected marginal revenue is positive.

From equations (22)–(24) of my original paper, we see that a risk-averse firm will have a smaller output under uncertainty if the *PIU* is satisfied at $q = q_c$, where q_c is the output of the firm under certainty. But at q_c, $E[MR(q_c, u)] = MC(q_c) > 0$. We conclude that the class of linear stochastic demand functions which satisfy (3) will exhibit the *PIU* for all relevant levels of q, and therefore firms facing such demand functions will produce less under uncertainty than under certainty.

My examination indicates that linear stochastic demand curves satisfying (3) *are* consistent with the *PIU* over the range of outputs relevant to analysis. Nonetheless, a methodological note might be in order. Korkie uses a common functional form (the linear demand function) to criticize an intuitively attractive behavioral principle (the *PIU*). One is reminded of a previous conflict—between the quadratic utility function and the Pratt-Arrow principle of diminishing absolute risk aversion. The outcome of that conflict was not the rejection of the principle, but rather of the quadratic utility function as a realistic description of tastes. Perhaps the real message of Korkie's paper is that the linear stochastic demand function should be used with caution.

[1] Korkie uses *Cov* (*TR*, *M*) as a measure of riskiness. Since my analysis does not introduce securities markets, it is difficult to compare his measure with my own measure of risk, as exposited in the Appendix of my paper. If, however, the firm's revenue is distributed independently of all other firms, Korkie's measure of risk is proportional to the variance of total revenue, since the firm is itself a component of M. In turn, variance of total revenue is equivalent to my definition of risk if the degree of uncertainty is small, and moments of the distribution of total revenue higher than the second can be ignored.

Nontraded Goods, Factor Market Distortions, and the Gains from Trade: Comment

By MURRAY C. KEMP and EDWARD TOWER*

In a recent article in this *Review*, Raveendra Batra considers a small country producing two traded goods and one nontraded good. He shows that for such a country, an increase in an already positive import duty may raise welfare and has asserted that this finding is contrary to a "standard theorem derived by Kemp."

We do not know of any standard theorem which is placed in jeopardy by Batra's finding. In that part of Kemp's *Pure Theory* referred to by Batra, it is stated that tariff-restricted trade is superior to no trade whether or not there are nontraded goods; and recently Kemp and Henry Wan have provided a fairly careful demonstration of the proposition. However the Kemp-Wan proposition seems to have little to do with Batra's. If Batra had been able to show that a tariff increment which finally eliminates

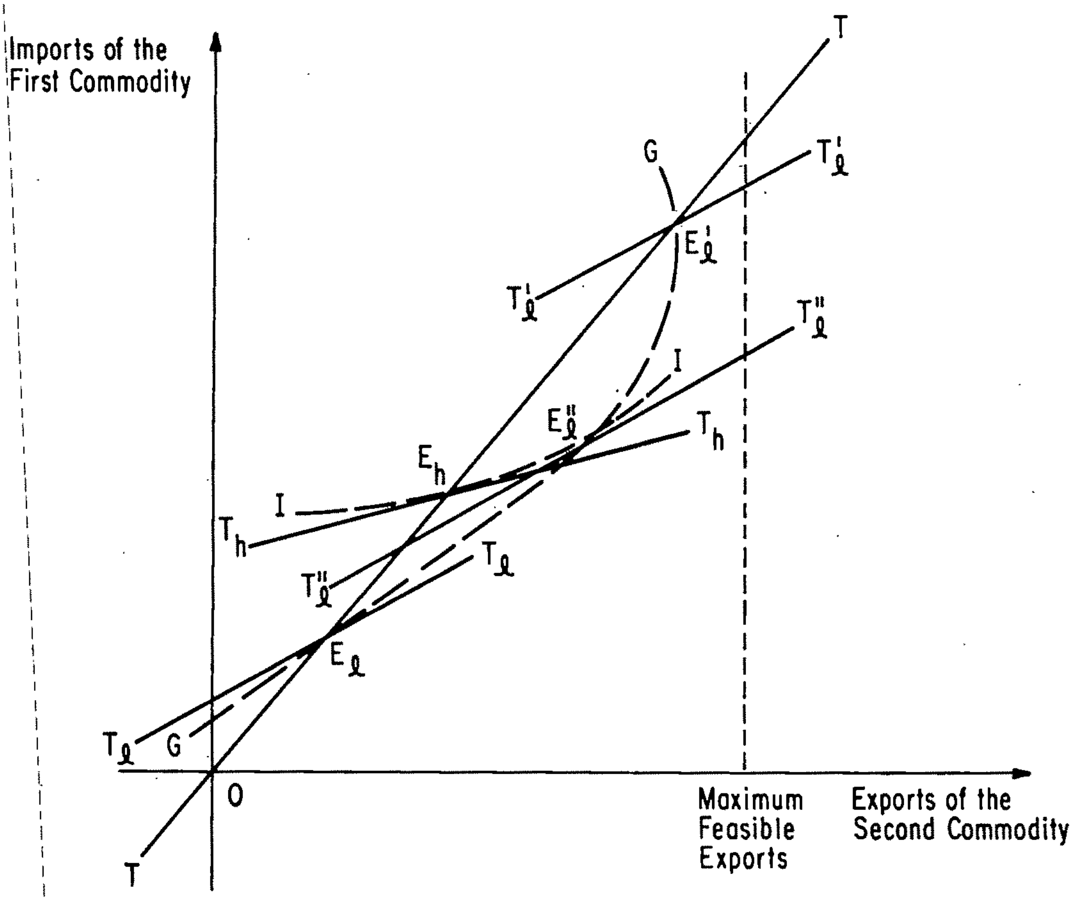

FIGURE 1

---

* Research professor of economics, University of New South Wales, and associate professor of economics, Duke University, respectively.

trade could raise welfare, then we should have agreed that the two propositions are in conflict. But this is precisely what Batra could not do. For from his equations (20) and (21) we obtain

$$\frac{1}{U_1}\frac{dU}{dt}=\frac{t}{1+t}\frac{dE_1}{dt}$$

and, if dt finally snuffs out trade, dE_1/dt is necessarily negative.

Moreover, the significance of Batra's finding must be assessed in the light of the fact that if there exists a tariff-distorted equilibrium with the property described by Batra, then there exists also an alternative preferred equilibrium without that property. That this is indeed a fact may be established by means of the accompanying trade indifference map. (Such a map can be drawn under any of the usual sufficient conditions, even when there are nontraded goods. The indifference loci have the usual curvature, and movements from one curve to another carry the usual welfare implications.) The given world terms of trade are indicated by the slope of the line TT; the lower-tariff domestic price ratio by the common slope of T_lT_l, $T_l'T_l'$, and $T_l''T_l''$; and the higher-tariff domestic price ratio by the slope of T_hT_h. The initial lower-tariff trade equilibrium lies, let us say, at E_l, where an indifference curve (not shown) is tangential to T_lT_l on TT. A new higher-tariff equilibrium lies, let us say, at E_h, where the indifference curve II is tangential to T_hT_h on TT. Evidently the community is better off at the higher-tariff equilibrium E_h than at the lower-tariff equilibrium E_l. Our diagram confirms Batra's algebra. Let us now consider the Engel curve GG defined by the lower-tariff domestic price ratio. This curve must pass through E_l and (given the curvature of II) through some point, say E_l'', on II to the right of E_h. After passing through E_l'', the curve may possibly continue to the right. However, it cannot cross the vertical line defined by maximum feasible exports. It therefore must eventually cross TT a second time, at say E_l'. Evidently, E_l' represents a second low-tariff equilibrium preferred to the first.

Nontraded Goods, Factor Market Distortions, and the Gains from Trade: Reply

By RAVEENDRA N. BATRA*

I take this opportunity to apologize to Murray Kemp for misinterpreting his theorem which was concerned with the comparison between restricted trade and no trade. I was wrong in thinking that this theorem examined the welfare implications of lower versus higher tariffs.

Coming now to the comments by Kemp and Edward Tower, I am afraid I do not find myself in complete agreement with them. In my paper I showed that in the presence of nontraded goods, a higher tariff will lead to a lower social welfare if the rise in tariff leads to a rise in the demand for imports, given, of course, that the country in question is small. Kemp and Tower, however, suggest that even if this is true, there exists an alternative low-tariff equilibrium with welfare level higher than that prevailing at the high tariff equilibrium.

I am not sure about the validity of this result because it depends on their assumption that the introduction of nontraded goods makes no difference to the properties of the trade indifference curve. I am not familiar with any study where the Kemp-Tower claim was established.

In what follows I show that although the trade indifference curve continues to be positively sloped even in the presence of the nontraded goods, its curvature need not be the same. First, I derive the equation of the trade indifference curve without nontraded goods and then show that if the social indifference curve is convex, then the underlying trade indifference curve is bowed-out towards the axis measuring exports.[1] In the presence of the nontraded goods, however, the convexity of the social indifference surface does not ensure the same curvature for the trade indifference curve.

Let C_i be the consumption of the ith traded good and X_i be its production, where $i=1, 2$. Assume that E_2 equals the amount exported of the second good, and E_1 is the amount imported of the first good. Then $C_1=X_1+E_1$, and $C_2=X_2-E_2$, so that a social utility function given by

$$U = U(C_1, C_2)$$

can be written as

$$U = U(X_1 + E_1, X_2 - E_2) \tag{1}$$

A trade indifference curve may be thought of a collection of points in the two dimensional E_2-E_1 space where utility is constant, and the marginal rate of substitution (U_1/U_2) equals the negative of the marginal rate of transformation (dX_2/dX_1), where $U_i=\partial U/\partial C_i$ is the marginal utility of the ith good and dX_2/dX_1 is the marginal rate of transformation. Thus, given that

$$\frac{U_1}{U_2} = -\frac{dX_2}{dX_1} \tag{2}$$

a utility level such as U_0 describes a trade indifference curve, where

$$U_0 = U(X_1 + E_1, X_2 - E_2) \tag{3}$$

The slope of U_0 is positive, because

$$dU_0 = U_1(dX_1 + dE_1) + U_2(dX_2 - dE_2) = 0$$

and in view of (2),

$$\frac{dE_2}{dE_1} = \frac{U_1}{U_2} \tag{4}$$

which is positive. The curvature of U_0 is defined by differentiating (4) with respect to E_1 and using (2) to obtain

---

* Professor of economics, Southern Methodist University.

[1] I am not aware of any study where the trade indifference curve has been mathematically derived.

$$(5)\ \frac{d^2E_2}{dE_1^2}=\frac{1}{U_2^3}[U_{11}U_2^2-2U_1U_2U_{12}+U_1^2U_{22}]\frac{dC_1}{dE_1}$$

where $U_{ij}=\partial U_i/\partial C_j\ (i\neq j)$. Now $dC_1/dE_1>0$ and the bracketed expression in (5) is negative because of the assumed convexity of the social indifference curve. Hence $d^2E_2/dE_1^2<0$ and it can be seen that the trade indifference curve will be bowed-out towards the exports axis, as in Figure 1 of the Kemp-Tower comment.

In the presence of the third nontraded good, where $C_3=X_3$ and the social utility function is

$$U = U(C_1, C_2, C_3)$$

the trade indifference curve is defined by

$$(6)\quad U_0 = U(X_1 + E_1, X_2 - E_2, X_3)$$

along with

$$(7)\quad U_1dX_1 + U_2dX_2 + U_3dX_3 = 0$$

Condition (7) is similar to condition (1) of the two-good case. The slope of the indifference curve as before is given by

$$dU_0 = U_1(dX_1 + dE_1) + U_2(dX_2 - dE_2) + U_3dX_3$$

so that in view of (7), $dE_2/dE_1=U_1/U_2$. Thus, in spite of nontraded goods, the trade indifference curve has the same positive slope as before. However,

$$(8)\quad \frac{d^2E_2}{dE_1^2} = \frac{1}{U_2^3}[U_{11}U_2^2 - 2U_1U_2U_{12} + U_{22}U_1^2]\frac{dC_1}{dE_1} + \frac{1}{U_2^3}[U_2^2U_{13} - U_2U_1U_{23} - U_2U_3U_{12} + U_3U_1U_{22}]\frac{dC_3}{dE_1}$$

Now the sign of dC_3/dE_1 and the bracketed expression of the second term in (8) is indeterminate. The sign of dC_3/dE_1, for example, depends on whether the nontraded good is a complement or substitute of the imported good. Hence the curvature of the trade indifference curve in the presence of the nontraded good is indeterminate.

NOTES

The eighty-eighth annual meeting of the American Economic Association will be held in Dallas, Texas, December 28–30, 1975. The Employment Registry and Center will open December 27. The meeting was originally scheduled for October, but has been changed in the interest of attracting greater attendance. The preliminary program of the meeting will appear in the September 1975 issue of this *Review*.

In October 1974, the American Economic Association began publication of *Job Openings for Economists* (*JOE*), a bimonthly listing of job vacancies. The response from both employers and subscribers has been excellent. Employers may list vacancies free of charge and are encouraged to do so. The 1975 subscription rates are U.S.A., Canada, and Mexico (first class): $6.00 junior member, $12.00 others; foreign airmail: $12.00 junior member, $18.00 others. See the advertising section of this issue for a subscription form.

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The ***deadlines for applications to be received*** in the office of the American Economic Association are: for meetings scheduled between June and September, *February 15;* for meetings scheduled between October and January, *June 15;* for meetings scheduled between February and May, *October 15.* Application forms may be obtained from Rendigs Fels, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

Fulbright-Hays Program for Senior American and Foreign Scholars

Applications will be accepted this spring for more than 550 university lecturing and advanced research awards during 1976–77 in over 75 countries under the senior Fulbright-Hays program, the Council for International Exchange of Scholars announced recently. Specialists in economics and business administration who are U.S. citizens and have a doctorate or college teaching experience are invited to indicate their interest in an award by completing a simple registration form, available on request from the Senior Fulbright-Hays Program, 2101 Constitution Ave., N.W., Washington, D.C. 20418. Registrants will receive a detailed announcement of the 1976–77 program in April. The deadline for application is July 1, 1975 and it is also the suggested date for filing for lectureships.

Each year Fulbright-Hays agencies abroad forward to the Council applications of senior foreign scholars who are interested in remunerative appointments for lecturing and postdoctoral research at American colleges or universities for temporary periods. The scholars are eligible for Fulbright-Hays travel grants if arrangements are confirmed for remunerative appointments. The Council would be pleased to receive at any time information regarding appointments available at American educational institutions for foreign scholars for temporary periods of three months to one year. A directory of senior Fulbright-Hays foreign scholars who are in the United States this academic year is available on request to the Council.

An international conference on Regional Science, Energy, and Environment will be held at Centrum voor Economische Studiën, Katholieke Universiteit te Leuven on May 23–24, 1975 in cooperation with Regional Science Association (International) and its Dutch speaking section. Primary emphasis will be on the interrelationship of regional and interregional growth, energy shortages, and environmental repercussions. Professor Leo H. Klaassen, President of the Netherlands Economic Institute and another well-known scholar from the United States will be guest speakers. For further information, write to M. Chatterji, School of Management, SUNY-Binghamton, Binghamton, New York 13901 or P. Van Rompuy, C.E.S., K.U.L., Leuven, Belgium.

The International Institute of Public Finance will hold its yearly conference at Nice, France, Sept. 8–12, 1975. The conference theme is "Public Economics and Human Resources." The chairman of the program committee is Professor Victor Halberstadt, Leiden University, Netherlands.

A conference on "The Epistemological Relationship Between Science and the Humanities" will take place in the spring of 1976 at Miami University, Oxford, Ohio, with a planning conference expected to be held in the spring of 1975. The introductory question proposed is "Does intuition/perception/creativity have a similar function in the work of scientists and of humanists?" Those interested in participating may write for information to Professor Britton J. Harwood, Conference Secretary, Upham Hall, Miami University, Oxford, Ohio 45056.

The Association for the Study of the Grants Economy will be sponsoring a session on "The Grants Economy and Income Redistribution" at the 1975–76 Meetings of the Eastern Economics Association. Those interested in presenting papers on this topic should submit abstracts of no more than 300 words before June 1, 1975 to Professor Charles Waldauer, Widener College, Chester, Pennsylvania 19013.

The Economics Institute announces the 18th session of its summer program to be held in Boulder, Colorado, May 29–August 20, 1975. The program is designed for international students who are coming to the United States to undertake graduate studies in economics and related fields, including agricultural economics, management, and business. Participants will have an opportunity to review and strengthen their academic preparation and English proficiency through intensive instruction adjusted to their individual needs. The Institute is sponsored by the American Economic Association and is conducted in cooperation with admitting universities and student sponsoring agencies. For further information write: Director, Economics Institute, University of Colorado, Boulder, Colorado 80302.

New Scholarly Journal

The *Journal of Behavioral Economics* is an interdisciplinary journal aimed toward academicians, both inside and outside the economics discipline, and to practioners in business and nonprofit organizations. The two goals of the journal are to further knowledge of real world economic phenomena by integrating psychological and sociological variables into economic analysis, and to promote interdisciplinary research by academicians and practitioners dealing in economics, the behavioral sciences, and public policy. The editors are particularly interested in substantial articles which are coauthored by scholars representing different social science disciplines. Correspondence concerning subscriptions or contributions should be addressed to Dr. Richard E. Hattwick, Center for Business and Economic Research, College of Business, Western Illinois University, Macomb, Illinois 61455.

Research group at the Quebec Professions Board would be interested to contact any department or institution undertaking economic, sociological, and political research on professions and professionalism for exchange of information. Please write to Mr. Alain Vinet, Research Coordinator, Office des Professions du Quebec, 930 Chemin Ste-Foy, Suite 780, Quebec 6, P.Q., Canada.

The National Tax Association-Tax Institute of America announces the 1974 award winners in the annual competition for outstanding doctoral dissertations in government finance and taxation. The $1,500 first prize award was won by Helen F. Ladd of Harvard University (now at Wellesley College) with her entry, "Composition of the Property Tax Base and Public Expenditure Behavior." Two honorable mention awards of $500 each were won by William A. Fischel of Princeton University (now at Dartmouth College), "Fiscal and Environmental Considerations in the Location of Firms in Suburban Communities," and Ann R. Markusen of Michigan State University (now at the University of Colorado), "The Economics of Social Class and Metropolitan Local Government." The members of the 1974 Selection Committee were Professors Harvey E. Brazer, Arthur D. Lynn, Jr., Oliver Oldman, and James A. Papke. Information on the 1975 award competition may be obtained from Professor James A. Papke, Department of Economics, Krannert Graduate School of Industrial Administration, Purdue University, West Lafayette, Indiana 47906.

The Rockefeller and Ford Foundations Program in Support of Population Policy Research in the Social Sciences is continuing its worldwide program of awards designed to encourage population policy research on the social and economic determinants and consequences of population growth and distribution, and broaden the understanding of the relationship between population variables, law, and economic and social policies. The program has a July 1, 1975 deadline for submissions. Awards will be announced in December. The proposed research can begin as early as March 1, 1976. For further information outlining application procedures, write to The Rockefeller-Ford Program for Population Policy Research, 111 West 50th Street, New York, New York 10020.

Deaths

William R. Curtis, Bureau of Employment Security, U.S. Department of Labor (retired), Falls Church, Virginia, Oct. 13, 1974.

Stephen Enke, Manager, Washington Office, TEMPO, General Electric's Center for Advanced Studies, Sept. 21, 1974.

Benton P. Gillingham, graduate student, University of Wisconsin-Madison, Aug. 1974.

Seymour E. Harris, professor emeritus, department of economics, University of California, San Diego, Oct. 27, 1974.

Retirements

I. O. Linger, professor of economics, Texas A&M University, Sept. 1974.

Rosser B. Melton, professor of economics, North Texas State University, Aug. 1974.

Visiting Foreign Scholars

John R. Broome, Birkbeck College, England: visiting associate professor, department of economics, University of Virginia, Jan. 1975.

Josua W. Grobbelaar, University of South Africa: honorary fellow, University of Wisconsin-Madison, spring 1975.

Donald I. MacKay, University of Aberdeen: visiting professor of industrial and labor relations, School of

Industrial and Labor Relations, Cornell University, spring term, 1975.

Bengt Olov Muthén, University of Uppsala: honorary fellow, University of Wisconsin-Madison, 1974–75.

Toshio Ohtani, Aoyama Gakuin University: honorary fellow, University of Wisconsin-Madison, 1974–75.

Peter Zweifel, University of Zurich: honorary fellow, University of Wisconsin-Madison, 1974–75.

Promotions

Marcelle V. Arak: senior economist, Research and Statistics Function, Federal Reserve Bank of New York, Sept. 6, 1974.

Huntley H. Biggs: associate professor of economics, Colorado State University, July 1974.

Edgar N. Browning: associate professor of economics, University of Virginia, Sept. 1, 1974.

E. Gerald Corrigan: adviser and secretary, Secretary's Office, Federal Reserve Bank of New York, Sept. 6, 1974.

Suzanne Cutler: assistant secretary, Secretary's Office, Federal Reserve Bank of New York, Sept. 6, 1974.

Neville J. G. Doherty: associate professor, School of Dental Medicine, University of Connecticut-Farmington, Oct. 1, 1974.

John R. Dominguez: associate professor, business economics and finance, University of California-Los Angeles, July 1, 1974.

R. B. Ekelund: professor of economics, Texas A&M University, Sept. 1974.

James P. Gander: professor, department of economics, University of Utah, July 1974.

Martin A. Garrett, professor of economics, College of William and Mary, Sept. 1974.

Eva Garzoui: professor, department of economics, Ithaca College, Feb. 21, 1974.

William J. Gasser: chief, Balance of Payments Division, Federal Reserve Bank of New York, Sept. 5, 1974.

Victor P. Goldberg: associate professor of economics, University of California-Davis, July 1974.

W. P. Gramm: professor of economics, Texas A&M University, Sept. 1974.

Michael J. Hamburger: adviser, Research and Statistics Function, Federal Reserve Bank of New York, Sept. 6, 1974.

John A. James: assistant professor, department of economics, University of Virginia, Sept. 1, 1974.

William A. Jordan: professor of managerial economics, Faculty of Administrative Studies, York University, July 1, 1974.

Robert R. Keller: associate professor of economics, Colorado State University, July 1974.

Sima Lieberman: professor, department of economics, University of Utah, July 1974.

Philip W. Ljungdahl: professor of accounting, Texas A&M University, Sept. 1, 1974.

Bennett T. McCallum: professor, department of economics, University of Virginia, Sept. 1, 1974.

John R. McKean: professor of economics, Colorado State University, July 1974.

Emily P. Mackall: professor, department of economics, Youngstown State University, Sept. 1974.

Peter Miles: associate professor of economics, Sir George Williams University, June 1, 1974.

Michael P. Murray: assistant professor, department of economics, University of Virginia, Mar. 1, 1974.

James F. Niss: professor of economics, Western Illinois University, Sept. 1974.

Terutomo Ozawa: professor of economics, Colorado State University, July 1974.

Scott R. Pearson: associate professor, Food Research Institute, Stanford University, Sept. 1974.

Frederick C. Schadrack, Jr.: vice president, Bank Supervision and Relations Function, Federal Reserve Bank of New York, Sept. 6, 1974.

R. Elberton Smith: professor of economics, California Polytechnic State University.

C. Peter Timmer: associate professor, Food Research Institute, Stanford University, Sept. 1974.

R. D. Tollison: professor of economics, Texas A&M University, Sept. 1974.

Hylke Van de Wetering, Iowa-Peru Project; professor of economics, Iowa State University, Sept. 1, 1974.

Korman C. Walzer: associate professor of economics, Western Illinois University, Sept. 1974.

Administrative Appointments

Evangelos Djimopoulos: deputy chairman, department of economics and finance, Fairleigh Dickinson University.

J. Edwin Faris, Washington State University: professor and head, department of agricultural economics and rural sociology, Clemson University, Oct. 1, 1974.

Alexander Garcia: chairman, department of economics and finance, Fairleigh Dickinson University.

Martin J. Gerra: special assistant to the president, Gallaudet College, 1974–75.

George A. Hay: director of economics, Antitrust Division, U.S. Department of Justice.

Rodger E. Karrenbrock: chairman, department of graduate accounting, Woodbury University, Sept. 9, 1974.

Tassos G. Malliaris: chairman, department of economics, Loyola University of Chicago, Sept. 1, 1974.

Vinod P. Maniyar, chairman, department of economics, Christopher Newport College.

Henry G. Manne, University of Rochester: director, Center for Studies in Law and Economics, University of Miami, fall 1974.

Paul E. Merz: chairman, department of economics, St. Louis University.

Chris Musun: chairman, department of graduate business management, Woodbury University, Sept. 9, 1974.

Larry G. Pointer: head, department of accounting, Texas A&M University, Sept. 1, 1974.

Richard N. Rosett, University of Rochester: dean, Graduate School of Business, University of Chicago.

Tom S. Sale III: head, department of economics and finance, Louisiana Tech University, Sept. 1, 1974.

David L. Scott: chairman, department of business and economics, Florida Southern College, fall 1974.

Bruno Stein: director, Institute of Labor Relations, New York University.

Morton Stelcner: chairman, department of economics, Sir George Williams University, Mar. 1974.

Max D. Stewart: dean, School of Business and Economics, Wilfrid Laurier University, July 1, 1974.

R. D. Tollison: chairman, department of economics, Texas A&M University, Sept. 1974.

Keith K. Turner; chairman, economics department, University of Nebraska-Omaha, Sept. 1974.

Richard J. Ward, Peat, Marwick, Mitchell and Co.: dean, College of Business and Industry, Southeastern Massachusetts University, Dec. 1, 1974.

Robert C. Yost: chairman, department of graduate international business, Woodbury University, Sept. 9, 1974.

New Appointments

Trevor Bain, Queens College: professor, University of Alabama, Aug. 1974.

James J. Benjamin, Virginia Polytechnic Institute: associate professor of accounting, Texas A&M University, June 1, 1974.

Jeffrey I. Berkowitz, Ohio State University: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

George C. Bitros: research associate, National Bureau of Economic Research, Sept. 20, 1974.

Dwight M. Blood: visiting professor, department of economics, Colorado State University, July 1974.

Jerry J. Bodily: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Gerald R. Bodisch: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Jon Breslaw: assistant professor of economics, Sir George Williams University, June 1, 1974.

James L. Butkiewicz: instructor, department of economics, University of Virginia, Sept. 1, 1974.

Dennis L. Chinn: assistant professor, Food Research Institute, Stanford University, Sept. 1974.

Thomas Chisholm, University of Missouri-Rolla: assistant professor, department of economics and business, Slippery Rock State College, Sept. 1, 1974.

Edward W. Clarke: lecturer, department of economics, School of Business and Economics, Wilfrid Laurier University, July 1, 1974.

Harold C. Cochrane: instructor, department of economics, Colorado State University, Sept. 1974.

Mark B. Cohen: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Kent A. Currie, University of Iowa: assistant professor of economics, Illinois Institute of Technology, Sept. 1974.

Phoebus J. Dhrymes: senior research associate, National Bureau of Economic Research, Sept. 16, 1974.

William M. Dugger, University of Texas-Austin: assistant professor, North Texas State University.

Rolf H. Dumke: lecturer, department of economics, School of Business and Economics, Wilfrid Laurier University, July 1, 1974.

Robert V. Eagly: economist, Foreign Research Division, Federal Reserve Bank of New York, Sept. 12, 1974.

William M. Edwards: instructor, department of economics, Iowa State University, July 1, 1974.

Charles M. Ellis, University of Alabama: North Texas State University, 1973–74.

Walter Enders: assistant professor of economics, Iowa State University, Sept. 1, 1974.

James A. Evenson: temporary assistant professor, department of economics, Colorado State University, Sept. 1974.

Norman Familant: instructor, department of economics, University of Virigina, Sept. 1, 1974.

Douglas Fisher: professor of economics, Sir George Williams University, June 1, 1974.

Mark B. Fitzsimmons: economist, Balance of Payments Division, Federal Reserve Bank of New York, Sept. 19, 1974.

Michael A. Flynn: instructor in economics, Wellesley College, Sept. 1974.

John Fox, Brown University: assistant professor, Youngstown State University, Sept. 1974.

Victor R. Fuchs: professor, department of economics, Stanford University, Sept. 1974.

Gasper A. Garofalo: assistant professor of economics, College of William and Mary, Sept. 1974.

Theodore A. Gebhard: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Lawrence J. Greenberg: economist, Balance of Payments Division, Federal Reserve Bank of New York, Aug. 1, 1974.

Peter R. Greenhalgh: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

J. R. Hanson II: assistant professor of economics, Texas A&M University, Sept. 1974.

Barry C. Harris: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Marilyn Hastings: assistant professor of economics, Western Illinois University, Sept. 1974.

Wallace E. Huffman: assistant professor of economics, Iowa State University, Sept. 1, 1974.

Gloria J. Hurdle: assistant professor of economics, Colorado College, Sept. 1974.

Richard A. Ippolito: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Philip Jacobs: assistant professor of economics, Sir George Williams University, June 1, 1974.

Parameswar Krishnakumar, University of Florida: assistant professor, department of economics and business, Slippery Rock State College, Sept. 1, 1974.

Paul S. Lande: assistant professor of city and regional planning, Ohio State University, Sept. 1974.

Irving F. Leveson, New York City Health Services Administration: senior professional staff, The Hudson Institute, July 1974.

H. H. Macaulay, Jr.: visiting professor of economics, Texas A&M University, Sept. 1974.

Allan S. Mandel: assistant professor, Lyndon B. Johnson School of Public Affairs, University of Texas-Austin, Sept. 1973.

Stephen Marglin: visiting professor of economics, Sir George Williams University, June 1, 1974.

Brian Maris, Kansas State University: visiting assistant professor, department of economics and business, Slippery Rock State College, Sept. 1, 1974.

Curtis H. Martin: research associate, National Bureau of Economic Research, July 1, 1974.

Robert T. Masson, Northwestern University: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

E. Scott Maynes, University of Minnesota: professor, department of consumer economics and public policy, Cornell University, Aug. 1974.

Stephen Mehay, visiting assistant professor, Sir George Williams University, June 1, 1974.

Frederick C. Meltzer: economist, Money and Finance Division, Federal Reserve Bank of New York, Sept. 19, 1974.

J. Meyer: assistant professor of economics, Texas A&M University, Sept. 1974.

Robert T. Michael: associate professor, department of economics, Stanford University, Mar. 1974.

Marc A. Miles, University of Chicago: instructor of economics, Loyola University of Chicago, Sept. 1, 1974.

Roger L. Miller, University of Washington-Seattle: professor of economics and associate director, Center for Studies in Law and Economics, University of Miami, fall 1974.

George R. Morrison, Graduate School of Business Administration, Rutgers University: visiting professor, department of economics, University of Viriginia, Jan. 14, 1975.

Frank Muller: associate professor of economics, Sir George Williams University, June 1, 1974.

William C. Myslinski: Economic Policy Office, Antitrust Division, U.S. Department of Justice.

Forest Nelson: research associate, National Bureau of Economic Research, June 1, 1974.

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment: his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3×5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

MAKE PLANS NOW

to attend the

1975 Meetings - Allied Social Science Associations

in

Dallas, Texas

Sunday, Monday, Tuesday,

December 28-30

Employment Center opens Saturday, December 27

This is a change from the October dates
previously announced.

Please note the 1976 ASSA meetings will be held in Atlantic City, September 16-18.

NEW

Caveat Emptor:
An Introductory Analysis of Consumer Problems
Roger M. Swagler, *Drake University*
February 1975 Paper 336 pages
Requiring no background in economics, this text applies fundamental principles of economic analysis to the actual here-and-now problems consumers face in the marketplace.

NEW

Money and Banking:
An Introduction to the Financial System
Thomas E. Van Dahm,
Carthage College
February 1975 Cloth [illegible] pages
[illegible]

NEW

Dialectical Economics:
An Introduction to Marxist Political Economy
Lyn Marcus, *Chairman, National Caucus of Labor Committees*
March 1975 Cloth 544 pages
An unprecedented approach to Marx's method and economic theory, this book explains, analyzes, and interprets Marxian economics through an interdisciplinary approach.
COMPLIMENTARY EXAMINATION COPIES NOT AVAILABLE.

NEW

Labor Market Segmentation
David M. Gordon,
New School for Social Research
Richard Edwards, *Harvard University*
Michael Reich, *Boston University*
January 1975 Paper 350 pages
This book examines persistent divisions within the labor force and proposes a theory of labor market segmentation to explain the continuing patterns of labor market differences.

The Theory of Microeconomic Policy
Nancy Smith Barrett,
The American University
1974 Cloth 384 pages
Rather than attempting to justify any particular economic system (capitalism, socialism, etc.), this intermediate-level text probes resource allocation per se, viewing optimal efficiency of allocation as a major economic goal.

"Public Enemy #1" – Inflation?

Is inflation really public enemy number one? Or is it merely the most superficial layer of a complex structure of interlocking problems?

Now the fourth edition of *The Economic Problem* offers your students the basic conceptual tools for answering questions like these and for understanding the functioning of the American economic system.

The Economic Problem

Robert L. Heilbroner
Lester C. Thurow

Always one of the most readable introductions to economics available, **The Economic Problem, 4th Edition** features some important changes that make economic theory even more accessible to your students:

- Lester Thurow, one of the nation's leading young economists, has joined forces with Robert Heilbroner. You can witness the benefit of their combined expertise in the strengthened section on microeconomics.
- The interdisciplinary orientation of **The Economic Problem** calls on history, philosophy, and sociology wherever appropriate to help trace the diversity of forces influencing the economic system.

- The long section on the historical background of modern economics has been condensed. Much of the material appears in boxed inserts in other chapters to add illustrative depth to the teaching material.

Also available as aids to student understanding are: a teacher's manual, transparencies, and a student workbook-reader compiled by the authors. 1975 704 pp. $13.95

OXFORD

Microeconomics

The Analysis of Prices and Markets

DONALD DEWEY, Columbia University. An introduction to the fundamental theorems of modern microeconomic theory, this text is the first to deal rigorously with the multiplant enterprise and market concentration. It contains an exceptionally detailed treatment of the theory of the firm, capital and interest, and the pricing of factor inputs, and welfare economics. While the axiomatic character of modern microeconomic theory is firmly emphasized, its tools are applied to a wide range of policy problems that interest students: conservation of natural resources, regulation of public utilities, labor legislation, contracts of professional athletes, antitrust, and cost-benefit analysis of public projects.

1975 352 pp. 95 graphs $9.95

New volumes in the

Economic Development Series

General Editor: GERALD M. MEIER, Stanford University

Agriculture and Structural Transformation

Economic Strategies in Late-Developing Countries

BRUCE F. JOHNSTON, Stanford University, and PETER KILBY, Wesleyan University. In this volume, an agricultural economist and an industrial economist examine the problems of designing agricultural strategies which will help overcome the acute poverty that characterizes low-income nations. They analyze the interrelationships between agriculture and other sectors of the economy and consider the special problems and opportunities associated with late development. Historical chapters highlight the experiences of Japan, the U.S., Taiwan, Mexico, and the Soviet Union while discussion of contemporary developing countries focuses on the development and policy issues associated with the Green Revolution in India and Pakistan.

Spring 1975 480 pp. graphs and tables
cloth $11.95 paper $6.95

Employment, Technology, and Development

AMARTYA SEN, London School of Economics and Political Science. Focusing on the interrelationships between institutions, technology, and employment, the author investigates the institutional factors which affect employment policy making: modes of production, patterns of ownership, and systems of employment. The techniques of project evaluation and shadow pricing are discussed with particular reference not only to institutional features, but also to political feasibility and behavioral characteristics. Professor Sen illustrates his approach in four appendices which reflect India's experience in the field.

Spring 1975 175 pp. cloth, prob. $7.50 paper, prob. $3.50

In the following trilogy of policy volumes in international political economy, Professor Meier offers students a provocative approach to major policy problems involved in establishing a new international economic order. By blending specific source materials with a more general analytical narrative, the author immerses students in a set of actual policy-making situations so they can become concerned with the controversy of foreign economic policy analysis and discover criteria for judging the merits of alternative courses of action.

Problems of a World Monetary Order

GERALD M. MEIER. "An excellent up-to-date account of the theoretical issues and institutional changes. Meier's synthesis of excerpts from newspaper and official reports, congressional hearings and journal articles is very successful." —Asim Erdilek, Case Western Reserve University

1974 318 pp. paper $4.95

Problems of Cooperation for Development

GERALD M. MEIER. This book explores the ways in which governments, international organizations, and multinational enterprises can cooperate in reorienting development strategy toward more effective "outward looking" policies and policies of "redistribution through growth." The specific policy problems are approached from the standpoint of new strategies of aid diplomacy, resources diplomacy, and commercial diplomacy.

1974 272 pp. paper $4.95

Problems of Trade Policy

GERALD M. MEIER. "Fine idea that brings out complexity of issues well. . . ." —John Sheahan, Williams College. "A novel treatment, superbly executed." —R. W. Trenton, Oklahoma State University. "It has the touch of the 'real world' that students are anxious to absorb. And it has the right balance of economics and political decision making that makes it interesting. Well done."—Refugio I. Rochin, University of California, Davis

1973 304 pp. paper $4.95

International Economic Reform

Collected Papers of Emile Despres

EMILE DESPRES; edited by GERALD M. MEIER. "This collection of the papers of the late Emile Despres (most of which were previously unpublished and, thus, not accessible) is a valuable book which I can recommend to any serious student of international economics. . . . The book demonstrates Professor Emile Despres' genius as an extraordinary economist."—Norman C. Miller, University of Pittsburgh, in the *Journal of Economic Literature*

HEALTH MANPOWER AND PRODUCTIVITY

The Literature and Required Research
edited by John Rafferty, *U.S. Department of Health, Education and Welfare*

Federal, state and local government officials hope to check spiraling medical care costs in part, through increased manpower productivity in the health services sector. Does the potential for such increased productivity exist? In response, Rafferty critically reviews the research literature dealing with health manpower productivity, placing special emphasis on economic literature. He discusses directions for future research which seem most promising and catalogs the important questions that still need to be answered. Notes, tables, figures.

CONTENTS: **Part I. Issues in Health Manpower Productivity.** 1. Manpower Substitution in Ambulatory Care/Uwe R. Reinhardt and Kenneth R. Smith. 2. Productivity and Economies of Scale in Medical Practice/Richard M. Scheffler. 3. Effects of Incentives on Physician Performance/Frank A. Sloan. 4. Patient Participation and Productivity in the Medical Care Sector/Fredrick L. Golladay. 5. A Review of Productivity in Dentistry/Paul J. Feldstein. 6. Occupational Licensure and Health Care Productivity: The Issues and the Literature/H.E. Frech. **Part II. A General Overview.** 7. Research on Health Manpower Productivity: A General Overview/Jack Hadley.
240 pp. $15.00

To order direct, write Order Dept., Lexington Books, D.C. Heath and Company, 2700 North Richardt Avenue, Indianapolis, IND 46219

The Welfare State and Equality
Structural and Ideological Roots of Public Expenditures
Harold L. Wilensky
Conservatives complain that the welfare state punishes the diligent and rewards the idle. Radicals and others argue that it fails to reduce poverty, achieve equality, or promote social justice. In his newest work Wilensky taps the relevant social science studies and provides a readable, provocative guide through this maze of welfare rhetoric. 176 pages, $8.95

Swedish Economic Policy
Assar Lindbeck
Mr. Lindbeck has focused mainly on economic policy in Sweden since the end of World War II. He places considerable emphasis on experiments with new tools to stabilize business fluctuations. 239 pages, $12.00

Ivory and Slaves in East Central Africa
Changing Patterns of International Trade to the Late Nineteenth Century
Edward A. Alpers
In this history of a complex international trade system in East Central Africa, the author suggests that the historical roots of underdevelopment must be sought in this system which was initiated by the Arabs in the fifteenth century. 304 pages, $13.50

Educated planning today leads to higher profits tomorrow.

1. ANALYSIS AND CONTROL OF DYNAMIC ECONOMIC SYSTEMS

By **Gregory C. Chow,** Princeton University

Presents a set of related techniques for analyzing the properties of dynamic stochastic models in economics and for applying these models in the determination of quantitative economic policy.

1975 336 pages (approx.) $19.95

2. LOCATIONAL DYNAMICS OF MANUFACTURING ACTIVITY

Edited by **Lyndhurst Collins,** University of Edinburgh and **David F. Walker,** University of Waterloo, Canada

Original essays interpreting changing patterns of industrial location in terms of historical and behavioral perspectives as well as contemporary theories and models.

1975 412 pages (approx.) Prob.$27.50

3. SOCIAL INFORMATION PROCESSING AND STATISTICAL SYSTEMS—CHANGE AND REFORM

By **Edgar S. Dunn, Jr.,** Resources for the Future, Inc., Washington, D.C.

This book analyzes the ways social data for management, public policy, and social science are acquired and processed and discusses the dilemmas this poses for those seeking to reconcile the need for individual freedom with the equally compelling need for social order.

1974 246 pages $12.50

4. SOCIAL INDICATORS AND SOCIAL THEORY
Elements of an Operational System

By **Karl A. Fox,** Iowa State University

Integrates theory, methods, and data across several social sciences, considering time budgets, behavioral setting, personality structure, occupational structures and many other areas to provide a rich theoretical perspective.

1974 328 pages $14.95

5. SPATIAL PERSPECTIVES ON INDUSTRIAL ORGANIZATION AND DECISION-MAKING

Edited by **F. E. Ian Hamilton,** University of London

Original research studies by well-known authorities focusing upon locational behavior by industrial organizations. Stresses types of industrial organization and decision-making behavior and their impact on industrial location patterns.

1975 533 pages $29.95

6. DOLLARS FOR NATIONAL GOALS
Looking Ahead to 1980

By **Leonard A. Lecht,** National Planning Association

Analyzes the changes in spending patterns during the 1960s, showing how these changes will influence a series of national goals and problems over the next decade.

1974 295 pages $17.95

7. STATISTICAL SAMPLING FOR AUDIT AND CONTROL

By **T. W. McRae,** The University of Bradford Management Centre

This book enables accountants to apply statistical sampling methods in auditing and financial control. It will help reduce the high set up and learning costs that statistical sampling incurs.

THE MOTIVATORS

CASEBOOK OF ECONOMIC PROBLEMS AND POLICIES: PRACTICE IN THINKING

By Rendigs Fels, Vanderbilt University,

and Robert G. Uhler, Federal Power Commission

176 pages, Paper, $4.50

"At last—a source book for open-ended questions"

That's what one educator had to say about this supplement for the principles of economics course. It's already in use by more than 125 colleges and universities across the country. It's a book that lays it on the line, challenges thoughtful responses from students concerning society's problems today: pollution; inflation; migrant workers; (even takes up ticket scalping). Uses the case method as pioneered by the Harvard Business School. As one of your colleagues sums it up: "An excellent way to integrate theory and practice in economics".

AN INTRODUCTION TO ECONOMIC ANALYSIS:

AN INNOVATIVE APPROACH TO THE STUDY OF ECONOMICS

By Donald W. Paden, University of Illinois

550 pages (tent.), Paper, $7.95 (tent.)

A self-contained package in one book.

Except for outside readings, here's a relatively self-contained text which includes the basic or core concepts of traditional economics analysis. Contains conventional text material, programmed material, lesson objectives, and test questions.

Emphasizes economic efficiency, employment, growth, inflation, money and foreign trade. Motivates students to participate from the standpoint of their own individual concepts and problems.

PRICES & MARKETS: A MICROECONOMIC TEXT

By Charles W. Baird, California State University, Hayward

400 pages (tent.), Cloth, $11.95 (tent.)

Emphasizes applications.

A new text for the junior/senior level. Presents microeconomic theory in a manner which convinces students it is just as applicable to real world phenomena as macroeconomics—even more applicable. Students are constantly motivated to ask about the usefulness of models used. Gives numerous applications of present value analyses such as investment in human and nonhuman capital, conservation, planned obsolescence, and predatory pricing.

Write for your complimentary examination copy. Please include course, number, average enrollment, and present text.

WP

OUTSTANDING ECONOMICS TEXTS FOR PARTICULAR ECONOMICS COURSES

THE INTERNATIONAL ECONOMY, Fifth Edition

P. T. Ellsworth, formerly University of Wisconsin; and
J. Clark Leith, University of Western Ontario

Now in its fifth edition, this leading text continues to provide comprehensive coverage of the principles of international trade and finance from both the historical and theoretical perspectives. Thoroughly revised and updated, the book traces the development of an international economy, the theory and policies of international trade, finance and balance of payments problems, and the Eurodollar market. Diagrams and illustrations help the student visualize theoretical principles.

1975 approx 608 pages

MONEY, BANKING, AND THE ECONOMY, Third Edition

John A. Cochran, Arizona State University

This comprehensive text is designed to introduce the beginning student to the fundamentals of money and banking. It is particularly concerned with promoting an understanding of the public policy issues, and the problems and institutions that characterize the macroeconomic policies of the 1970's. The book achieves a balance between the theoretical and institutional approaches in its treatment of monetary and banking history, the money market, commercial banking, the Federal Reserve System, central banking, inflation, and the international monetary system. Emphasis throughout is on current problems and institutions, making this a complete, modern and intriguing introduction to money and banking.

1975 approx 640 pages

COMPARATIVE ECONOMIC SYSTEMS

Richard L. Carson, Carleton University

In this exciting and interesting presentation, COMPARATIVE ECONOMICS SYSTEMS focuses on the theoretical and analytic aspects of the different economic systems in the world today. By discussing comparative economic systems in terms of economic principles and concepts, the book explains general theory and describes the various national systems as they relate to the theory.

It first analyzes the universal economic problems of scarcity and distribution, then treats various economic solutions in terms of economic priorities. The way in which specific countries apply these economic solutions is described in conjunction with each solution. Numerous graphs, charts, and tables appear within the text.

PRAEGER
SPECIAL STUDIES

MARKETING IN JAPAN
A Management Guide
M. Y. Yoshino
Foreword by *Patrick M. Boarman* and
Richard C. King
This practical analysis of consumer trends and market opportunities in Japan includes extensive surveys of major institutions and their functions, the Japanese distribution system, and recent market developments. Sponsored by the Center for International Business, Pepperdine University, Los Angeles.
176 pp. Jan., 1975 ISBN 0-275-09170-8 $15.00

CHINESE AND SOVIET AID TO AFRICA
Edited by *Warren Weinstein*
Surveys trends in Chinese and Soviet aid to Africa. Finds Chinese aid, more controlled than Soviet aid, is labor intensive, and therefore usually more relevant.
316 pp. Jan., 1975 ISBN 0-275-09050-7 $20.00

FOREIGN PRIVATE MANUFACTURING INVESTMENT AND MULTINATIONAL CORPORATIONS
An Annotated Bibliography
Sanjaya Lall
This annotated guide to the growing English-language literature on foreign private manufacturing investment and the multinational corporation includes both theoretical and applied studies. References mainly, but not exclusively, post-date 1965.
212 pp. Jan., 1975 ISBN 0-275-05570-1 $16.50

ECONOMIC GROWTH IN DEVELOPING COUNTRIES—MATERIAL AND HUMAN RESOURCES
Proceedings of the Seventh Rehovot Conference
Edited by *Yohanan Ramati*
Authorities discuss three essential development themes—resources, technology, and income distribution; external constraints on development; and planning and implementation. Published in cooperation with the Continuation Committee of the Rehovot Conference.
522 pp. Feb., 1975 ISBN 0-275-09300-x $25.00

THE FUTURE OF COMMERCIAL BANKING
Edited by *Wray O. Candilis*
Foreword by *Senator John Sparkman*
Examines commercial banking in relation to the public. Includes chapters on the changing structures of banking; bank holding companies; community affairs; automation and employment; competitive forces.
218 pp. Jan., 1975 TC 0940 ISBN 0-275-28760-2
$16.50

CAPITAL ACCUMULATION AND TECHNOLOGY TRANSFER
A Comparative Analysis of Nigerian Manufacturing Industries
D. Babatunde Thomas
Examines the relationship between capital formation and technological progress and explores its influence on value added per man in the manufacturing sector. Based on a case study of 800 Nigerian companies in 19 industries.
170 pp. Jan., 1975 TC 0960 ISBN 0-275-28771-8
$15.00

YUGOSLAV ECONOMIC DEVELOPMENT AND POLITICAL CHANGE
The Relationship between Economic Managers and Policy-Making Elites
Richard P. Farkas
This analysis of the present Yugoslav system's organizational and functional aspects links the growing power of the Enterprise Directors with those of the policy-makers, and places them into the context of national economic programs and international economic relations.
150 pp. Feb., 1975 ISBN 0-275-28780-7 $13.50

ECONOMIC GROWTH AND EMPLOYMENT IN VENEZUELA
An Analysis of an Oil-Based Economy
Mostafa F. Hassan
Emphasizes the need in developing countries for employment policies consciously aimed at attacking the unemployment problem. Explains the contributing factors in Venezuela's high rate of unemployment at a time when the economy is rapidly expanding.

8 new economics texts–

HUTCHINSON **Money, Banking, and the United States Economy, 3rd Edition**

Harry D. Hutchinson, University of Delaware, has written Money, Banking, and the United States Economy, 3rd Edition, with today's student in mind. It is simple, readable, complete, and entirely rewritten to focus on the economic crises in the mid-1970's. Intended for use in a one-semester undergraduate course in the economics of money and banking, the book contains a broad range of monetary topics competently developed with a balanced mixture of institutional and theoretical content.
March 1975 approx. 560pp. $12.95

BARRETT **The Theory of Macroeconomic Policy, 2nd Edition**

This text shows students that macroeconomic policy must have a theoretical basis. Nancy Smith Barrett, American University, presents traditional macroeconomic theory in the context of a policy planning model. In this revision there is an expanded and updated treatment of the theory of inflation and its policy implications, with a chapter on the theory of wage and price controls. New material on unemployment and labor market policy has been added. More attention is focused on monetarism and other non-Keynesian approaches.
January 1975 approx. 480pp. $12.95

COHEN/CYERT **Theory of the Firm: Resource Allocation in a Market Economy, 2nd Edition**

Kalman J. Cohen, Duke University, and Richard M. Cyert, Carnegie-Mellon University, have designed this text as a concise statement of economic knowledge about the firm. It emphasizes the theoretical development from neoclassical theory to modern relations. Students going through the book will have comprehensive knowledge about the status of the economist's views on the firm.
February 1975 approx. 608pp. $13.95

ZAHN **Macroeconomic Theory and Policy**

Frank Zahn, Bowling Green State University, presents a new approach to intermediate macroeconomics — organized on the premise that once the basic theoretical and technical apparatus of an aggregate economic model is familiar to students, analysis of aggregate economic problems and considerations of policy alternatives can be undertaken with relative ease.
February 1975 approx. 320pp. $12.95

—from prentice-hall

ISARD **Introduction to Regional Science**

This text represents one of the first introductions to regional science ever written. Walter Isard, University of Pennsylvania, combines elementary material covering urban and regional economics, economic geography, city and regional planning, land use and environmental management, and relevant materials from other social sciences as they contribute to an understanding of how a city and region grows and develops.
January 1975 approx. 544pp. $11.95

SIMON **Applied Managerial Economics**

Julian L. Simon, University of Illinois presents the latest methods in decision analysis, but handles all problems with simple tabular methods that require no mathematics beyond arithmetic. Renders the theory of managerial economics operational and useful.
January 1975 approx. 560pp. $15.95

SNODGRASS/WALLACE **Agriculture, Economics, and Resource Management**

Milton M. Snodgrass, Mexico State University, and L.T. Wallace, University of California, outline a complete introduction to agricultural economics and agricultural business management.
January 1975 approx. 544pp. $13.95

TUCKER **Essentials of Economics**

James F. Tucker, Virginia Polytechnic Institute and State University, presents material providing not only a broad basis for better understanding of the American economic system, but also the fundamental tools needed for more effective decision-making regarding this system.
November 1974 368pp. paper $6.95

Lancashire in Decline

A Study in Entrepreneurship, Technology, and International Trade

By Lars G. Sandberg. An examination of the precipitous and disastrous decline, following World War I, of what has been described as the world's first modern industry and the major factor in the emergence of Great Britain as the world's leading industrial power, that looks beyond the customary charges of technological backwardness and entrepreneurial ineptitude usually invoked to explain the eventual collapse of the Lancashire cotton textile industry to essay an analysis, based on an impressive body of statistical data, of international developments in drastically altered economic circumstances and a rapidly changing world. Illus. $15.00

Environmental Quality and Society

Edited by Richard A. Tybout. A collection of original essays that examine the issues posed by the deterioration of the environment within a social context, on the assumption that it is through changes in our societal institutions that the growing threat to life will finally be reversed. The authors include Durward L. Allen, Arthur A. Atkisson, Jr., Robert Bierstedt, Paul F. Brandwein, Adolf Ciborowski, W. Wesley Eckenfelder, Jr., Morten Gorden, S. Smith Griswold, Orris C. Herfindahl, Charles L. Hosler, G. Evelyn Hutchinson, Justin W. Leonard, Michael McCloskey, Senator Gaylord Nelson, Edward Stainbrook, and Richard A. Tybout. $7.50

The Soviet Foreign Trade Monopoly

Institutions and Laws

By John Quigley. An intensive study of the administration of what is the initial effort on the part of any government to conduct and to regulate, as a monopoly of the state, the foreign trade of an entire nation, which traces its evolution from its beginnings in 1918 in a decree signed by Lenin, who feared the effect on the fledgling socialist economy of capitalistic economic aggression from without, into the vast and complex bureaucracy that is the Soviet Trade Ministry of today. $15.00

From the publishers of the *Journal of Money, Credit, and Banking.* Published quarterly in February, May, August, and November. Subscription rates: $14.00 per year; student subscriptions, $8.00 per year.

Economic Integration in Central America
Empirical Investigations
JEFFREY B. NUGENT

Nugent studies the experience of five countries in the Central American customs union in order to assess both the effects of the customs union itself and the potential benefits of supranational policy planning for developing countries. By constructing and analyzing smallscale econometric models of each country and the region as a whole, he finds that benefits from customs union participation are larger than what has generally been assumed. $14.00

The World between the Wars, 1919-1939
An Economist's View
JOSEPH S. DAVIS

"Absolutely magnificent! Such thoroughness such wit and wisdom. Nobody can pretend to know about those years until they have read this book." —*Samuel Ellot Morison*

The author here examines the fiscal policies in Europe and the U.S. at the time of the stock market boom and collapse and pinpoints those political and psychological misjudgements made by key individuals who helped to shape the depression's unfortunate course. $16.00

THE UNCERTAIN SEARCH FOR ENVIRONMENTAL QUALITY

A Case Study in the Failure of Modern Policy Making

Bruce A. Ackerman and Susan Rose Ackerman, James W. Sawyer, Jr., Dale W. Henderson

"...an extraordinary study of the policy-making process. Better than any other analysis that I know of, it deals with the complex interaction among technical, economic, bureaucratic, political, and legal factors that are characteristic of the policy process....A landmark analysis which will be widely used for years to come...."—Henry S. Rowen, Professor of Public Management, Stanford University

367 pages $13.95

ECONOMIC FOUNDATIONS OF POLITICAL POWER

Randall Bartlett, Williams College

Refuting the traditional assumption that public policy is determined independent of conflicting private interests, this book examines the relationship between government and the economic agents of an industrialized society.

192 pages $8.95

MULTINATIONAL OIL

A Study in Industrial Dynamics

Neil H. Jacoby

Provides crucial information on how we got into the present energy crisis, then gives powerful alternative solutions. Jacoby presents new information on the foreign oil industry since World War II, including the development, structure, and performance of multinational corporations in the foreign oil market.

304 pages $3.95, paper

INCOME AND IDEOLOGY

An Analysis of the American Political Formula

Joan Huber and William Form, both, University of Illinois at Urbana-Champaign

Compares and contrasts the belief systems of poor, rich and middle-income groups, based on findings from a study of whites and blacks in a midwestern city and of Anglos and Chicanos in a rural Texas town. Areas which receive particular emphasis include: the causes of wealth and poverty, the importance of money, the "American Dream" of equal opportunity, and the extent to which Americans feel they can influence politics by voting. 226 pages $8.95

THE AMERICAN ECONOMY

An Historical Introduction to the Problems of the 1970's

Edited by Arthur M. Johnson, University of Maine at Orono

This book examines the quality of life, the morality of wealth, and the development of the American economy. Other contemporary issues presented in historical readings and explanatory essays include: poverty and the distribution of income; the tools used to manage and control our economy, their efficacy and relevance today; the role of private enterprise; and the prospects for the United States in a confused and changing world economy. 275 pages $4.95, paper

Announces its 18th Summer Program f

INTERNATIONA

Graduate Student

in ECONOMICS and RELATED FIELD

University of Colorado, May 29-August 20, 197

With sessions beginning May 29, June 16 (Main Session), and July 1

The Institute is specially designed for students from other countries w are planning to undertake studies at universities in the United States America in economics and related fields, including business and agricultur economics, during the subsequent academic year. Intensive instruction, a justed to individual student needs, is offered in each of the following co course areas:

- ECONOMIC THEORY
- ENGLISH
- MATHEMATICS
- STATISTI
- ECONOMIC PROBLEMS AND POLICIES
- BUSINESS ORGANIZATION AND MANAGEMENT

The primary purpose is to help students review and strengthen their academ preparation and English proficiency. However, the core course curriculu is supplemented by field trips and social and recreational activities design to acquaint them with campus and community life in the U.S.A.

The Institute is conducted in cooperation with admitting universities a sponsoring agencies. Proof of admission to an acceptable graduate progra in the following academic year is required.

Macroeconomics is more than just that...

Revised and up-dated!

MACROECONOMICS

SECOND EDITION

Norman F. Keiser, San Jose State University

The aim of **Macroeconomics** is not only to provide a thorough grounding in intermediate macroeconomic theory, but also to convey its significance in relation to current problems in American society.

Professor Keiser begins the text with a discussion of economic goals, the values they reflect, and the role of macroeconomics in attaining them.

Policy issues and empirical studies are integrated into the building of the macro model, making the material more realistic and relevant to students.

The second edition of **Macroeconomics** has been thoroughly up-dated and made more concise. The last chapter, "Fiscal and Monetary Policies From 1960-1974," is entirely new. Recent economic events have been incorporated into the text wherever relevant.

February, 1975 512 pages Order Code 31922

Accompanying **Macroeconomics** or any other standard macro text is **Macroeconomics: Problems and a Survey of Theory, Second Edition.** This workbook and brief review of macroeconomic theory has been revised and reorganized to match the text.

INTRODUCTORY MACROECONOMICS

Peter C. Dooley, University of Saskatchewan

This basic introduction to macroeconomic theory:

- Begins with fundamental microeconomic concepts and principles as a foundation for developing macroeconomic theory.
- Provides thorough and concise treatment of the core of macroeconomic theory: consumption, investment, government, foreign trade, and money and interest.
- Relates economic policy to the interrelated problems of unemployment, inflation, and balance of payments.

Published 1974 192 pages Order Code 31757

ECONOMICS: MAINSTREAM READINGS AND RADICAL CRITIQUES

SECOND EDITION

Edited by **David Mermelstein,** Polytechnic Institute of Brooklyn

In this collection, articles by mainstream economists are juxtaposed with radical critiques. Students are presented with economic controversies and encouraged to reach their own conclusions.

Contributions are from prominent economists such as Milton Freidman and Paul Samuelson; radical economists such as Thomas Weisskopf and Paul Baran; and social commentators such as Ralph Nader, Robert Townsend, and William Domhoff. Topics include Sexism, Consumerism, Ecology, and the Industrial State.

The Participatory Economy

An Evolutionary Hypothesis and a Strategy for Development

By JAROSLAV VANEK. "This is a companion volume to Vanek's *General Theory of Labor-Managed Market Economies.* Here he handles the same theme in a simpler but broader way, describing how the growing influence of the workers leads to a gradual takeover of the management of producer units, and the impact of this on society.... This well-organized and clearly written work ... is valuable not only for students of economics, but also for those seeking a general knowledge of the social sciences."—*Library Journal* $2.45
(Also available in cloth/$10.50)

—Also by Jaroslav Vanek—

A MODEL OF MACROECONOMIC ACTIVITY
Volume I: The Theoretical Model
Ray C. Fair, *The Cowles Foundation, Yale University*

Ray C. Fair develops a dynamic model of macroeconomic activity based on microeconomic foundations which accounts for all flows of funds in the system and for wealth and capital gains effects. This model overcomes many of the serious limitations of the standard Keynesian static-equilibrium model. Mr. Fair carefully presents the model in various stages to aid in understanding it and a number of important implications for the specification of empirical models are discussed. Volume II will present a relaxed empirical model.

Contents:
1. Introduction. 2. Banks. 3. Firms. 4. Households. 5. The Government and the Bond Dealer. 6. The Dynamic Properties of the Model. 7. A Static-Equilibrium Version of the Model. 8. Conclusion.

an E . . .
is an E . . . is an
E . . .

No! An E is more than an E.

In the case of ECONOMICS — An Analysis of Principles and Policies, Second Edition, by Hailstones and Brennan, an E might well stand for Expectation, Enlightenment, Enrichment, Emphasis, and Explanation — for these are all hallmarks of this important new edition.

The real measure of a truly good textbook lies in its effectiveness as a teaching and learning tool, upon which the instructor can build an effective, interesting, and challenging fundamentals of economics course. Here are a few reasons why this new textbook merits your attention:

- the distinguished team of authors who are competent economists
- the appropriately balanced theoretical, graphic, and analytical treatment of economic fundamentals
- the unique blending of traditional theories and insights with contemporary economic issues
- the depth of coverage of macro-, micro-, and U.S. and world economics
- built-in flexibility through the wide variety of supplementary materials that correlate with the basic textbook

Request an examination copy of ECONOMICS — An Analysis of Principles and Policies, Second Edition, from the South-Western office serving you and you'll see why an E is more than just an E!

Your colleagues comments on various chapters of

THE ECONOMY

By Bradley R. Schiller

2 "... exceptionally well written. The transition from micro to macro concepts is exceedingly well done. I particularly liked the repeated references to production possibility curves in developing the concepts."

—*Augustus Shackelford*
El Camino College

11 "A much better discussion than most others on the subject ... goes beyond mere description of the Phillips Curve to analysis of its origins and alternative policies."

—*Melville J. Ulmer*
University of Maryland

12 "... the chapter on energy and the environment is indicative of the blend of lively exposition and illustrations that ... characterize the book as a whole."

—*Wallace Oates*
Princeton University

14 "An excellent chapter, particularly on the weaknesses of the theory of diminishing marginal utility. This chapter not only brings basic economic theory to the student but helps him to analyze the faults of applying a scientific theory to human behavior."

—*Wesley Booth*
San Antonio College

15 "The micro races along, captures the students' interest and imagination."

—*Ernest Nadel*
University of California, Berkeley

20 "Schiller is very clear and convincing on horizontal monopoly/oligopoly power."

—*Walter Adams*
Michigan State University

25 "... clearly and concisely written. They manage to present the problems of poverty and welfare as analytic economic problems without losing a sense of the political and ideological concerns which make them issues at all ... the text has the important virtue of treating the reader with respect and speaking to him in a mature and intelligent tone."

—*Michael Piore*
Massachusetts Institute of Technology

26 "... contains one of the most realistic treatments of the problems of blacks and women in education and in the job market I have seen by an economist. It should give beginning students in economics exactly what they need to deepen their understanding of the economic and social issues at stake."

—*Barbara Bergman*
University of Maryland

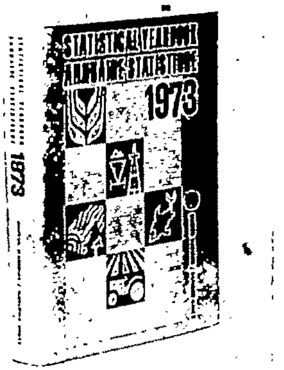
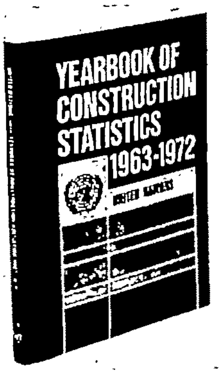
PUBLICATIONS FROM UNITED NATIONS

STATISTICAL YEARBOOK 1973
Important compilation of statistics from countries throughout the world covering a wide range of economic and social subjects, including: population, agriculture, manufacturing, construction, transport, trade, balance of payments, national income, education and culture. Improved statistical coverage has enabled the *Yearbook* to widen the territorial scope of many of its tables and to provide more comprehensive and accurate world and continental aggregates.
Order No. E.74.XVII.1 Clothbound $35.00



COMPENDIUM OF HOUSING STATISTICS 1971
This world-wide compilation of housing and related statistics is prepared by the Statistical Office of the United Nations with the assistance of the Population Division and in co-operation with the Centre for Housing, Building and Planning. Its main purpose is to make available, information derived from national housing censuses and to provide for a more complete interpretation of this information than would otherwise be possible by presenting other data that have a bearing on the housing situation. These include data on population and its growth, dwelling construction, the cost of housing, and capital formation in housing.
Order No. E/F.73.XVII.4 $14.50



YEARBOOK OF CONSTRUCTION STATISTICS 1963-1972
This is the first in a new series of annual compilations of statistics on world construction activity and has been prepared to make available the information derived from annual surveys in this field undertaken all over the world.

The data presented in this publication are primarily based on replies to the Construction Statistics Questionnaire of the United Nations, distributed in 1972 for the first time. The information received has been supplemented in a few instances with data obtained from published sources, as well as with the work undertaken by the Statistical Office on the compilation of construction statistics in the United Nations *Statistical Yearbook*.
Order No. E.74.XVII.9 Clothbound $18.00

DEMOGRAPHIC YEARBOOK 1973
The twenty-fifth issue of the *Demographic Yearbook* contains 1973 statistics of area, population, natality, mortality, nuptiality and divorce for every country of the world, latest available data on expectation of life and a 7-year trend of international arrivals and departures. Data on the economic characteristics of the population are shown, including labour force participation rates by age and sex as well as various cross-classifications of population by industry, occupation, status, age and sex.
Order No. E/F.74.XIII.1 Clothbound $38.00

United Nations Publications, Room LX-2300, New York, N.Y. 10017
or
Palais des Nations, 1211 Geneva 10, Switzerland

• *New, Spring 1975*

GROWTH OF THE MODERN AMERICAN ECONOMY by STUART BRUCHEY, *Allan Nevins Professor of American Economic History, Columbia University*. Paperback, 160 pages, $3.95.

How a country with an agricultural economy moved to an industrial one in less than 200 years, and how it managed to raise the standard of living of its citizens to the highest in the world are the major themes of this concise overview. Questions related to continued growth are discussed.

SOCIAL WELFARE: A HISTORY OF THE AMERICAN RESPONSE TO NEED by JUNE AXINN and HERMAN LEVIN, both *University of Pennsylvania*. Paperback, 304 pages, $6.95.

A unique effort to assess the economic, social, political, and philosophical implications of the historical evolution of social welfare in America — supported by documents and illustrations.

The Second Edition of

ECONOMICS

AN INTRODUCTION TO TRADITIONAL AND RADICAL VIEWS

E. K. Hunt and Howard J. Sherman

This comprehensive introduction to economics, the first to compare traditional and radical views in a clear exposition for beginning students, has been updated and substantially revised in response to suggestions made by first edition users. Material on such topics as pure competition and monopoly, monopoly power, government and inequality, the economics of discrimination, and business cycles and unemployment has been thoroughly rewritten. New material has been added on aggregate economic problems and the institutional setting, consumption, wage-price controls, and waste and pollution. February 1975. Tentative: 672 pages $8.95/paper. Instructor's Manual. Part I will again be released in a separate volume. **PROPERTY AND PROPHETS: The Evolution of Economic Institutions and Ideologies, Second Edition:** February 1975. Tentative 192 pages; $3.95/paper.

Also New in 1974-1975

INTRODUCTION TO ECONOMETRICS: Principles and Applications

SIMPLY OUTSTANDING

ECONOMICS AND SOCIETY

By Leonard W. Weiss,
University of Wisconsin, Madison

Simplicity. It's a guiding principle in Weiss. Each chapter of ECONOMICS AND SOCIETY opens with an explanatory paragraph . . . and closes with a summary. In between, your students will discover—with accumulating interest—economics as it has never before been introduced. Weiss is built upon a sound economic base. Yet its theory remains as simple as possible.

Most of it concerns supply and demand, or aggregate supply and demand. These concepts are applied repeatedly to such policy issues as **monopoly, discrimination, labor market, balance of payments,** and **public goods.**

Some texts are long, or diffuse, or incomplete for a one-quarter or one-semester introductory economics course, Weiss is **just right.** And Weiss is one author who knows how to express himself. Students will take to his lucid style at once. You have to read it to believe it.

Discover Weiss. You'll find that the outstanding coverage of ECONOMICS AND SOCIETY is structured with care around a single idea: Simplicity. January 1975 544 pages (tent.) $10.95

MACROECONOMICS:
Measurement, Theory, and Policy

By Michael C. Lovell, **Wesleyan University**

Lovell **is** macroeconomics. Designed for intermediate and upper-level courses, he stresses modern theoretical advances while analyzing unemployment, inflation, balance of payments, disequilibrium, business cycles, growth, and more.

The text is structured for maximum flexibility—with core chapters designated, key concepts and exercises at the end of chapters and appendices for more in-depth coverage of specific topics. All in all, Lovell provides a solid presentation of macroeconomic concepts. Spring 1975 550 pages (tent.) $13.95 (tent.)

THE ECONOMICS OF INTERNATIONAL BUSINESS

By R. Hal Mason, **UCLA,** Robert R. Miller,
University of Iowa, Dale R. Weigel,
University of Iowa and **International Finance Corp.**

Mason/Miller/Weigel shows how the tools of economic analysis can be applied to the problems faced by managers of international business. It's the only text • to discuss technology selection, and financial decision in the international firm • with an up-to-date treatment of international monetary affairs • which approaches international business from a moderately analytical viewpoint.
1975 444 pages $14.95

THE ECONOMICS OF ENVIRONMENTAL POLICY

By A. Myrick Freeman III, **Bowdoin College,**
Robert H. Haveman, **University of Wisconsin,**
and Allen V. Kneese,
Resources for the Future, Inc.

This brief text presents the facts of environmental problems, places problems in an economic framework, and stresses the attainment of effective environmental policy through an economic incentive strategy.

New editions that reflect the new economic realities

INTERNATIONAL ECONOMICS

A Policy Approach

SECOND EDITION

Mordechai E. Kreinin, *Michigan State University*

As up-to-date as the current oil crisis, this new Second Edition of *International Economics* provides a comprehensive, truly international introduction to world finance and trade. Professor Kreinin emphasizes policy and the analysis of general principles, using the most important trading nation in the world—the United States—as his reference point for evaluating policy alternatives. The policy materials in this second edition reflect important developments in international economics through mid-1974—among them, the trade problems of developing countries, the 1974 GSP of the European Communities, the proposed GSP of the United States, the new international currency system and Euro-dollars, the balance of payment adjustments under fluctuating exchange rates, and the monetary approach to devaluation. As in the previous edition, the book thoroughly covers present currency arrangements, analyzes the balance-of-payments problem, offers suggestions for reforms of the monetary system, and explains the principles governing world trade, the role of trade organizations, and selected trade problems among developing nations.

500 pages

. . . and the latest economic thought

THE EVOLUTION OF ECONOMIC THOUGHT

THIRD EDITION

Jacob Oser and William C. Blanchfield, *Utica College of Syracuse University*

Now in its Third Edition, this readable, comprehensive survey of economic theory covers 72 economic theorists and their ideas from the 16th century to the present; it provides biographical sketches of each theorist as well as substantial quotations from their work and background material on the thought of each age. The authors evaluate each major school in terms of its social milieu, its essential ideas, and its impact on its own time and later periods.

Major changes, additions, and improvements in this Third Edition include a greater emphasis on the interrelationships among the different schools of economic thought; revised and expanded sections on Marx, Engels, and the Utopians; a revised section on monopolies; and extensive discussion of Galbraith's latest works, *The New Industrial State* and *Economics and the Public Purpose*; new treatment of our changed perception of economic problems as a result of the Keynesian revolution; and a new section on post-Keynesian economics that explores the contributions of Samuelson, Arrow, and the school of mathematical economics.

look at our statistics for 90 days . . . FREE

☐ **INTRODUCTORY STATISTICAL ANALYSIS**

By Donald L. Hamett, *Indiana University*, and James L. Murphy, *University of North Carolina* 1975 575 pages 103 illustrations

Designed for a beginning course in statistics for business, economics, and social science students, this text provides a mixture of intuitive explanation, examples, and mathematical rigor for students who have had exposure to college mathematics. Throughout the writing and classroom use of this text, careful attention has been given to readability, organization, and flow of material.

Numerous examples and problems show the usefulness of statistics in everyday decision making situations. Each chapter ends with a "Review Problems" section which reinforces the chapter material and an "Exercises" section which is more challenging. An Instructor's Manual is available.

☐ **INTRODUCTION TO STATISTICAL METHODS, SECOND EDITION**

By Donald L. Hamett, *Indiana University* 1975 640 pages 108 illustrations

The carefully selected level of presentation in this text allows students to make ample use of prior courses in college algebra, finite math, and calculus. A broad range of statistical topics are covered with the basic methods and applications for statistical analysis in business, economics, and most social science disciplines. An Instructor's Manual is available.

☐ **APPLIED STATISTICS FOR BUSINESS AND ECONOMICS**

By Henrick J. Malik and Kenneth Mullen, *University of Guelph, Ontario* 1975 565 pages 161 illustrations

The emphasis is on clarity and simplicity in this elementary text for students in business and economics with a high school algebra background. All concepts are introduced by examples, followed by a thorough discussion, and then more examples for complete clarification. An Instructor's Manual is available.

Lecture Notes in Economics and Mathematical Systems

New and forthcoming

Volume **100**

Cluster Analysis

A Survey

Edited by *B. S. Duran* and *P. L. Odell*

This volume represents the first book on cluster analysis — the partitioning of a given set into subsets satisfying certain optimality conditions. Similar to factor analysis, it is an important tool for all investigations (e.g. in economics, the life sciences, psychology) which involve the organization of large amounts of empirical data.

1974. vi, 137p. paper/**$7.40**

Volume **103**

Optimal Subset Selection

Multiple Regression, Interdependence, and Optimal Network Algorithms

By *D. E. Boyce, A. Farhi,* and *R. Weischedel*

This book deals with the problem of selecting items (variables, transportation links, facility locations, etc.) from a member set of all available or possible items so as to optimize an objective function subject to a budget or size constraint. Three optimization subset selection problems are discussed: optimal regression analysis; interdependence analysis; optimal network analysis. Computer programs are also included.

1974. xiii, 187p. paper/**$8.20**

Volume **104**

A Neo-Keynesian Theory of Inflation and Economic Growth

By *S. Fujino*

The author investigates processes of cyclical fluctuations, inflation and economic growth, combining short-run analysis with longer term investigation about the economic development. The book develops a new dynamical neoclassical theory of investment and is of particular interest due to today's concern about growth, inflation, and "stagflation."

1974. v, 96p. paper/**$7.40**

Volume **107**

Control Theory Numerical Methods and Computer Systems Modeling

International Symposium, Rocquencourt, June 17-21, 1974

Edited by *A. Bensoussan* and *J. L. Lions*

The contributions to this volume are primarily devoted to the mathematical aspects of control theory and related fields.

1975. approx. 770p. paper/approx. **$21.80**

1974 256 pages Cloth $14.50

NATIONAL MONETARY POLICIES AND THE INTERNATIONAL FINANCIAL SYSTEM

Edited by Robert Z. Aliber

Economists from several nations consider the inadequacies of the Bretton Woods System and focus on the inconsistency between member nations' policies and the international financial system.

Studies in Business and Society series

1974 352 pages Cloth $16.50

LESSONS FROM JAPANESE DEVELOPMENT

An Analytical Economic History

Allen C. Kelley and Jeffrey G. Williamson

Breaking new ground in development studies, this work is a unique economic history of Japan from 1887 to 1915, the "formative years" of Japan's modern economic growth. The authors address the question: Can or should Japan be taken as a "model" for today's developing nations to follow?

Providing Adequate Retirement Income

Providing Adequate Retirement Income
Pension Reform in the United States and Abroad

by James Schulz, Guy Carrin, Hans Krupp, Manfred Peschke, Elliott Sclar, and J. Van Steenberge

Experts analyze social security pension systems in the United States, Sweden, Germany, Belgium, and Canada, showing how innovative systems abroad suggest alternative options for the United States. They examine the current economic status of the elderly in this country, project future retirement income, and explore alternative policy options, including "dynamic pensions," based upon a nonpoverty definition of income adequacy. *Published for Brandeis University Press.* $15.00

University Press of New England Box 979, Hanover, N. H. 03755

WHAT IS TO BE THE ECONOMICS OF TO-MORROW?

In a new Hobart Paperback

"The Cambridge Revolution: Success or Failure?" Professor Mark Blaug of the University of London argues that:

> "The claim that Cambridge UK is launching a revolution in economic thought, on the scale and in the spirit of the Keynesian Revolution, is largely a piece of misleading advertising, which evaporates as soon as its accomplishments to date are closely examined."

In contrast,

> "Anyone who has been attentive to the resurgence of the neo-classical research programme . . . can hardly doubt that there is life yet in the concepts of maximisation, equilibrium, substitution and all the other tricks of the trade of mainstream economics. Cambridge UK, however it tries, cannot get along without these ideas and in that lies the overwhelming superiority of the neo-classical tradition in economic thought."

An IEA Hobard Paperback **price $6.95**

Other critiques of fashionable thinking from IEA, and especially of the macro-economic monopsony have been

"Macromancy"
(Hobart Paper 55 price $2.50)

in which Douglas Rimmer attacked the misuse of GNP as the measure of economic progress and

"Macro-economic Thinking and the Market Economy"
(Hobart Paper 56 price $2.50)

in which Professor L. M. Lachmann rebuked both the latterday Ricardians at Cambridge (UK) and the neo-classicals at Cambridge (USA) for inter alia formalism, which enables some economists "to dispense with individuals, the differences between their minds and the inequality of men in general."

There will be further contributions to the counter-revolution in economy theory from the IEA in 1975. Write for 1975 catalogue

An Opportunity For Departure

Yes, an opportunity to pursue a bold, new, and effective approach to economics. A refreshing departure from past approaches to economic concepts—approaches that failed miserably in their basic purpose—that of teaching economics to students.

ECONOMICS—The Science of Common Sense by E. V. Bowden is designed to accomplish one basic objective—to present economic principles as simply and as clearly as possible. To this end, we anticipate the greatest success. You'll agree when you examine ECONOMICS—The Science of Common Sense.

IASP titles in economics

John Kenneth Galbraith and the Lower Economics

Second, Expanded Edition

Myron E. Sharpe, **Editor of CHALLENGE: The Magazine of Economic Affairs**

"The best review I have yet seen of Galbraith's works . . . Sharpe [in the first edition] has succeeded in highlighting Galbraith's contribution to economic thought, while exposing to critical scrutiny the weakest parts of his analysis. I'm happy to recommend this book.

—**Robert L. Heilbroner**

This edition contains a new section evaluating Galbraith's **Economics and the Public Purpose**, and includes a lengthy interview with Galbraith.

$7.95

The Socialist Economies of the Soviet Union and Europe

Marie Lavigne, **University of Paris**

"Marie Lavigne's book is both thoroughly competent and of a sufficiently high standard to raise French Sovietology to the level of English or American works on the same subject." —**Revue Economique**
(Reprinted in **Economic Journal**)

This encyclopedic study devotes major attention to the Soviet economic system, and is unusually detailed in describing the other socialist economies and in drawing upon them for important cross-national comparisons.

Dr. Lavigne's publications include **Capital in the Soviet Economy, The Problem of Prices in the Soviet Union** (with Prof. H. Denis), and **COMECON: From Cooperation to Integration of the Socialist Economies.**

$20.00

Monetary Cooperation Between East and West

Adam Zwass, **Vienna Institute for Comparative Economic Studies**

Foreword by George Garvy

A systematic study of the instruments and processes of East-West financial relations based on a critical analysis of the money, credit and foreign trade systems of the East European countries and of their Council for Mutual Economic Assistance.

Dr. Zwass occupied managerial positions in the central banking systems of Poland and the USSR. From 1963 to 1968 he was a Counsellor in the COMECON Secretariat in Moscow, where he was responsible for the work of the International Bank for Economic Cooperation.

Advertising and Socialism

The Nature and Extent of Consumer Advertising in the Soviet Union, Poland, Hungary and Yugoslavia

Philip Hanson, **University of Birmingham**

The most thorough and detailed study to date of consumer advertising in socialist economies. The author employs a substantial amount of new data — much of which has been obtained from extensive interviewing of managerial personnel — to examine and compare the organization, nature, and purposes of advertising in four socialist countries.

Dr. Hanson is the author of **The Consumer in the Soviet Economy.**

$15.00

Land Reform and Economic Development in China

A Study of Institutional Change and Development Finance

Victor D. Lippit, **University of California at Riverside**

A new analysis that makes a significant contribution to the economics of the Chinese Revolution and to development theory generally.

Professor Lippit shows how a poor country managed simultaneously to raise the share of national income devoted to investment and increase living standards. He focuses on the use of the "surplus" — the capital or property share of national income — to redirect income flows, thereby to shift consumption from luxuries to necessities and increase public investment.

Still a Dream
The Changing Status of
Blacks Since 1960
Sar A. Levitan,
William B. Johnston,
and Robert Taggart

The most comprehensive review of the changing social and economic status of Blacks in the United States during the critical years since 1960, this definitive work investigates how changes occurred, how much change took place, and how public policy affected the transformations. The authors argue that conditions of the 1970s have offset some of the gains of the previous decade. $15.00

Introduction to Urban Economics

DOUGLAS M. BROWN, *Georgetown University*

This textbook provides the student with a knowledge of, and the tools for, analysis of contemporary urban economic problems. The history, growth, and development of cities is examined in detail, with particular emphasis on the relationship between urban problems and economic analysis.

- Provides complete coverage of interurban and intraurban economic analysis, requiring only a background in economic principles.
- Surveys the economic history of cities from tribal organizations to the American city today, with special attention given to colonial cities.
- Integrates theoretical and empirical analysis of urban markets with a lively discussion of contemporary problems.
- Examines the causes and possible solutions for critical urban problems from the point of view of economic analysis.
- Presents a wide spectrum of theoretical and empirical analysis with a minimal use of mathematics.

TECHNICAL CHOICE, INNOVATION AND ECONOMIC GROWTH

Essays on American and British Experience in the Nineteenth Century

PAUL ALLAN DAVID, *Professor of Economics, Stanford University*

Self-contained, related essays focusing on specific industries and individual productive units—from a New England textile mill to a mid-Victorian grain farm. By "one of the leaders of the movement which has been dubbed 'The New Economic History.' His writings invariably display a mastery of historical literature relevant to the problem at hand."—NATHAN ROSENBERG, *The University of Wisconsin*
Cloth $21.00 Paper $5.95

LATE NINETEENTH-CENTURY AMERICAN DEVELOPMENT

A General Equilibrium History

JEFFREY G. WILLIAMSON, *Professor of Economics, University of Wisconsin*

Professor Williamson probes issues central to American economic history, such as the role of the railroads, the distribution of income, development of the frontier and capital market development. His findings often differ from the established "truths" because here for the first time this critical period is analyzed with sophisticated models and extensive data. $19.50

RATIONAL ECONOMIC MAN

A Philosophical Critique of Neo-Classical Economics

MARTIN HOLLIS, *Lecturer in Philosophy, University of East Anglia*

EDWARD J. NELL, *Professor of Economics, New School for Social Research*

The authors attack the neo-classical theories of economics and the positivist theories of knowledge upon which they rely. They argue convincingly for a rationalist philosophy and a classical or Marxian form of economics. $14.95

OFFICERS FOR 1975

President

Robert Aaron Gordon,
University of California, Berkeley

President-elect

Franco Modigliani,
Massachusetts Institute of Technology

Vice-Presidents

Martin Bronfenbrenner, Duke University
Charles L. Schultze, University of Maryland

Secretary-Treasurer and Editor of Proceedings

Rendigs Fels, Vanderbilt University

Managing Editor of the American Economic Review

George H. Borts, Brown University

Managing Editor of the Journal of Economic Literature

Mark Perlman, University of Pittsburgh

Elected Members of the Executive Committee

Irma G. Adelman, University of Maryland
Robert L. Heilbroner, New School for Social Research
Andrew F. Brimmer, Harvard University
Paul M. Sweezy, Monthly Review
Carolyn Shaw Bell, Wellesley College
Burton A. Weisbrod, University of Wisconsin

Ex Officio Members

Kenneth J. Arrow, Harvard University
Walter W. Heller, University of Minnesota

Counsel

Donald F. Turner, Harvard University

THE AMERICAN
ECONOMIC REVIEW

VOL. LXV MAY, 1975 NUMBER 2

PAPERS AND PROCEEDINGS

OF THE

Eighty-seventh Annual Meeting

OF THE

AMERICAN ECONOMIC ASSOCIATION

San Francisco, California
December 28–30, 1974

Program Arranged by ROBERT AARON GORDON
Papers and Proceedings Edited by RENDIGS FELS
and C. ELTON HINSHAW

Copyright American Economic Association, 1975

PRINTED BY GEORGE BANTA COMPANY, INC.

Publication Office: Menasha, Wisconsin 54952

Executive Office: American Economic Association
1313 21st Avenue South, Nashville, Tennessee 37212

Inquiries and other communications regarding membership, meetings, and the general affairs of the Association, as well as orders for the publications and permission to reprint, should be addressed to Rendigs Fels, Secretary of the American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

Changes of address should also be sent to the Secretary at the address given above. To be effective, notice must reach the office by the 1st of the month prior to the month of publication. The Association cannot be responsible for copies lost due to failure to report change of address in time.

Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

No responsibility for the views expressed by authors in this *Review* is assumed by the editors or the publishers, the American Economic Association.

Membership dues of the Association are $23 a year, $18.40 of each year's dues being in payment of a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature.* The *American Economic Review* is published five times a year (March, May, June, September, and December) with four quarterly issues, the *Papers and Proceedings* of the annual meetings, the *Directory*, and supplements, and is sent to all members of the American Economic Association as one of the privileges of membership, as is the *Journal of Economic Literature* (four quarterly issues per year). Subscriptions by nonmembers (libraries, institutions, etc.) are $34.50 annually. Only subscriptions to both publications will be accepted. Single copies of the *Review* and *Journal* may be ordered from the Executive Office.

Price $9.50

THE purpose of the American Economic Association, according to its charter, is the encouragement of economic research, the issue of publications on economic subjects, and the encouragement of perfect freedom of economic discussion. The Association as such takes no partisan attitude, nor does it commit its members to any position on practical economic questions. It is the organ of no party, sect, or institution. Persons of all shades of economic opinion are found among its members, and widely different issues are given a hearing in its annual meetings and through its publications. The Association, therefore, assumes no responsibility for the opinions expressed by those who participate in its meetings. Moreover, the papers presented are the personal opinions of the authors and do not commit the organizations or institutions with which they are associated.

Editors' Introduction

THIS volume contains the papers and proceedings of the eighty-seventh annual meeting of the American Economic Association. "Proceedings" concern the business activities of the Association—the annual membership meeting, the twice yearly meetings of the Executive Committee, and reports of various Association officers and committees—and, as with the "Notes" section in each issue of the *American Economic Review*, are published in the hope that members will be informed of, and will participate in, the Association's affairs.

The "Papers," which constitute the greater part of this volume, are roughly equivalent to two regular issues of the *American Economic Review*, but are published under quite different procedures. An explanation of current Association policies concerning papers for the annual meetings may therefore be of some interest.

Early in the year the Association's President-elect (in 1974 R. A. Gordon, in 1975 Franco Modigliani) sets in motion the process which culminates in the December presentation and May publication of the papers. After consultation and comments, both volunteered and solicited, from a wide range of persons, the President-elect decides on the topics of sessions (roughly twenty) at which papers will be presented, sets limits on the length of papers and invites persons to organize these sessions. Each session organizer in turn invites, again after consultation, several persons (usually two or three in number) to give papers on the topic of the session in question, and asks others to give comments on the papers. The papers, or rough drafts, are supposed to be sent to the editors of the *Papers and Proceedings* by November 15; we then read them and return them to their authors with comments and suggestions. In late December the papers and comments are read at the Association's meetings; we ask the authors to send us the final versions of their papers by January 2. After giving the final versions further scrutiny, we then in almost all cases send them to the printer to be published. (We do not generally publish discussants' comments, however, unless there is some special reason to do so.)

Thus, the rules under which these papers are published are quite different from those concerning articles appearing in regular issues of the *Review*. The papers published here are invited, not contributed; except in unusual circumstances they must be less than 4,000 (and sometimes 3,000 or even 2,000) words in length; each author is asked to avoid highly technical discussion and instead to contribute a paper which will be intelligible to economists not specializing in the subject it discusses. While we do edit (sometimes extensively) most papers to improve content and style and to satisfy space constraints, we do not subject papers to any refereeing process, and publication of any paper which we receive prior to the final printer's deadline and which satisfies (or can be cut to satisfy) space requirements is virtually guaranteed.[1]

These policies are advantageous in a number of respects. The volume of papers can be published without the long delays inherent in publication by regular journals, and it consists of relatively short papers which concern a wide variety of subjects and can be understood by nonspecialists. Authors get a chance to report briefly on research just completed, to discuss topical subjects in an informal and engaging way, and to summarize longer forthcoming publications; readers get a chance to browse among a large number of articles which are outside their major areas of interest but which are not as specialized or ponderous as those sometimes found in regular journals. And while the papers are not scrutinized in the way regular journal articles are, they are (or are at least intended to be!) nontechnical, and thus do not need the thorough refereeing usual for articles submitted to journals.

RENDIGS FELS
C. ELTON HINSHAW

---

[1] We would refuse to publish such a paper only if we felt that it was utterly without merit; no paper has yet been rejected on these grounds. However, the Executive Committee has established another ground for rejection: if a paper cannot be cut to meet space requirements, we ask the author either to authorize us to submit it to the managing editor of the *Review* to be considered for publication (subject to the usual refereeing process) in a regular issue of that journal, or to withdraw the paper and submit it elsewhere.

RICHARD T. ELY LECTURE

Income Distribution—Can Economists Help?

By ALICE M. RIVLIN*

Since it is always safer to make predictions in a field other than one's own, I want to start this lecture with a political prediction, namely, that income shares and distributional aspects of public actions are going to become a major focus of policy debate in the next few years. I am not predicting how that debate will come out—just that it will take place. I want to talk this evening about how economists can be useful in raising the debate from a shouting match to something approaching an informed argument over real issues.

In choosing this topic I am implicitly contending that economists ought to try to make themselves useful and that public policy will be "better" if they do. Both these points are arguable, but I do not intend to get into that argument. Nor do I feel it necessary to defend the proposition that income is a reasonable proxy, if not for happiness, at least for economic well-being, and hence its distribution is worth talking about.

There are several reasons for thinking that the public and its political representatives are likely to be increasingly concerned about income shares. First is the continuing fact that instant communication, especially televisual communication, has made everyone more conscious of what others have and do not have, while at the same time rising real incomes and constant relative shares have widened the absolute gap between the fairly rich and the fairly poor. It is not just those at the bottom of the heap who are more conscious than ever of what they are missing. Increasingly—perhaps by reaction to the political emphasis on extreme poverty in the 1960's—it is those near the middle who seem most militantly concerned about their share. The double devastation of inflation and recession, moreover, exacerbates the concern with income shares, since everyone, including stock brokers, feels abused when real income is falling.

The second reason for the mounting concern over income shares is the apparent rise in group identities of Americans and the new political sophistication of these groups in pressing their advantage through the law, collective bargaining, public relations, political influence, and even civil disobedience. Groups learn effective tactics from each other and we can look forward in the next few years to organized group pressure at all levels by blacks, Chicanos, native Americans, women, Polish-Americans, old people, young people, blue-collar workers, public employees—and maybe even middle-aged white males.

Third, there are some demographic-social forces that may move the Lorenz curve of family income farther from the 45-degree line and increase public awareness and political concern with inequality. The rising average age of family heads could have this effect, but a more dramatic disequalizing force may well be the changing status of women. The proportion of families headed by women has been increasing and is likely to continue to do so. This need not be seen as a pathological development—it may reflect an increasing capacity of women to fend for themselves in the marketplace and a real increase in the welfare of those involved, but it clearly makes the distribution of family income more unequal than it would otherwise be. A more important effect of women's changing status may be to increase the inequality of income among husband-wife families. As long as wives have been secondary earners in every sense of the word, their earnings have had a generally equalizing effect on family income. But this effect would be reversed if a major increase occurred in the proportion of wives with a permanent, lifelong attachment to the labor force and an earnings distribution similar to that of husbands. People with high earning capacity tend to marry each other, and this tendency might well be increased if job status became a more central part of the average woman's life. In a world in which professionals and managers married each other, while unskilled workers did the same, and in which male and female patterns of working and earnings were similar, the concentration of money income among husband-wife families at the high end of the scale would be even greater than it is now, and the income share of those at the bottom would be lower.

---

* Member of the Economics Studies Program of The Brookings Institution. The views expressed are mine and not necessarily those of the officers, trustees, or other staff members of The Brookings Institution.

The political focus on distributional questions that I expect for the next few years need not be an overt fight about redistributing money income as such through taxes or transfers or other policies explicitly designed to do just that. It might take the form of increased concern with and friction over the distributional impact of other policies sure to be on the national agenda, such as health insurance, energy conservation, pollution, and measures to combat inflation and recession.

Assuming that I am right in this political speculation, it seems to me that there are four sets of questions that the public and the politicians might reasonably ask a useful group of economists.

1. What is happening?
   How great is income inequality and which way is it moving?
   What are the effects of current government programs?
2. What would be better?
   Presumably no one wants economists telling them what the distribution of income ought to be, but they might reasonably expect them to be helpful in defining alternative norms and discussing how varying degrees of equality might be expected to affect other objectives.
3. Why are things as they are?
   Economists worth their pay ought to provide a workable theory that explains why the distribution of income has the shape it has and why it is changing or not changing.
4. What can we do about it?
   Useful economists ought to spell out some policy options and estimate their effects, not only on the distribution of income but on the size of the pot to be distributed.

Clearly this is a large order and the questions are intimately interrelated. One needs a theoretical framework to explain facts and to make predictions either about the effect of alternative distributions on economic behavior or about the efficacy of particular policies for redistributing income. Nevertheless, it may be useful to address these questions sequentially and ask what economists now have to say about each of them and where we might profitably concentrate our future efforts.

I. What is Happening?

To the layman the question may sound simple: Is the distribution of income becoming more equal or more unequal? But one of the main contributions of economists has been to point out that the question is anything but simple and that it cannot be answered without a painstaking effort to define some terms.

First, it matters what *units* one is talking about. The distribution of income among individuals is meaningless because people live in groups and pool their incomes, so we must look at the income of families, households, or perhaps "spending units." These groupings, however, are of varying size and composition. Hence, in considering the degree of inequality some adjustment ought to be made—although it usually is not—for the number of people in the unit and perhaps for the varying needs of different kinds of people. Second, it makes a difference what is *counted as income*. It matters whether one measures income before or after taxes and whether one sticks to cash or adds estimates of income in kind and services of major durable goods such as houses. In particular, it matters how one counts the services of government. It seems absurd to count cash transfers, such as social security, as income while omitting near-cash benefits, such as food stamps. But should one also count the use of roads and the putative protection of nuclear missiles? Third, it matters what *time* period one is talking about. A year is an arbitrary accounting period that is too short for some purposes and too long for others. Short-period inequality is no less "real" than long-period inequality—a kid without a dime cannot get a stick of bubble gum with his permanent income—but it may cause a different degree of concern and call for different remedies. Finally, there are many *measures of inequality* and they may move in opposite directions at the same time. The one most people seem to find comprehensible, the Lorenz curve, can give ambiguous results when the real world is ambiguous. It can show, for example, that the size distribution of income has moved farther from equality at the bottom and closer to it at the top. Moreover, a lot of people who say they are concerned about inequality are really concerned about poverty or income inadequacy, not about inequality per se, and poverty has to be defined somehow, either as inability to afford a specified collection of goods and services at current prices or as a state of deprivation relative to what some major fraction of the population enjoys.

Economists have a smashing record of pointing out all of these problems in measuring income inequality, but, with one major exception, a rather dismal success rate in collecting the refined data we all keep saying is so necessary to answer the questions. The exception is the quantum leap in knowledge about the economic status of the poor that has taken place in the last decade, in large part through the tireless and often unglamorous efforts of economists and other social scientists to refine definitions and goad the government into collecting new information about the low-income population—who they are, where they are, and how they live. We may not have solved the problem of poverty, but we certainly know a lot more about it than we did in 1964.

On other aspects of income inequality, some of the gaps in the data seem pretty preposterous. For example, federal taxes now constitute about 20 percent of gross national product and federal transfer payments to individuals in cash and in kind are running about 10 percent (U.S. Dept. of Commerce). Despite the clear potential of these instruments to alter income shares, there are no data regularly collected on the distribution of income after federal taxes; cash transfers to individuals are inadequately reported; and federal transfers in kind are not counted as income at all. It is quaintly anachronistic that the census counts as income the value of homegrown vegetables, but not the value to the recipient of medicare payments. Moreover, despite the interest of economists in the permanent income hypothesis and the obvious fact that it is hard to tell much about a family's well-being from one year's income, almost all income distribution data relate to single years and we are only beginning to make serious attempts to follow particular families for longer periods.

Why blame economists? Don't economists do the best they can to analyze the data that the government gives them? Yes, that's just the point. The passivity of economists about data collection is at least part of the reason why the right information rarely seems to be available for answering questions like: What's happening to the distribution of income? Disdain for data collection is built into the value and reward structure of our profession. Ingenious efforts to tease bits of evidence from unsuitable data are much applauded; designing instruments for collecting more appropriate information is generally considered hack work.

The Michigan Longitudinal Survey and the immense effort that has gone into income maintenance and other experiments connected with the concern for poverty may mark the beginnings of a new trend from passivity to activism in data collection by economists. But not much effort is yet going into maximizing the usefulness of obvious sources such as the census.

But enough of economists' shortcomings as data collectors. What do the available facts enable us to say about the distribution of income and how it is changing? The big news, of course, is that there is no news. Real incomes have been rising over the years at respectable if not spectacular rates, but measures of inequality have hardly changed at all since World War II. In a world in which change is normal—in which people are used to revolutions in technology and communications, racial and sexual upheaval, baby boom and baby bust, decline of cities and mushrooming of suburbs—the constancy of the size distribution of income stands out as remarkable.

The number of people living in poverty, of course, may be said to have declined as long as one associates poverty with a fixed level of real income. But if one defines the poverty line as, say, half the median income, one finds that the proportions in poverty have remained constant for a quarter of a century—19.0 percent of families had less than half the median income in 1947, 19.4 percent in 1972—while the absolute gap between the poor and the median family has widened. (See U.S. Bureau of the Census 1973b.)

The distribution of male earnings actually appears to be getting less equal, although most of the change relates to increases in the proportion of younger men in the labor force and in the frequency of part-time work by younger and older workers (Peter Henle). But it is the size distribution of family income that really seems to be stuck in a rut. The bottom 20 percent of families gets 5 percent of total income and the top 20 percent gets a little more than 40 percent—the numbers have hardly varied at all since the late 1940's. (See U.S. Bureau of the Census 1973a.) Whether one regards the distribution as acceptable or outrageous, one can hardly help being surprised that it remains so constant in the face of other changes, especially the growth of federal transfer programs whose benefits go mainly to low-income people. In-kind transfers do not count as income—if they did they would be slightly equalizing—but transfer income, such as social security and public assistance, does count. These payments have risen substantially in the last two decades and now amount to about $100 billion, one-third of the federal budget and about 9 percent of personal income (U.S. Treasury Dept.). One might well ask why they have not had a visible equalizing effect on the distribution of family income.

The answer appears to be that the preponderance of federal transfers has gone to retired persons and a small part to women heading families; that the recipients, especially old people, are better off, both absolutely and relatively than they used to be; but that the equalizing effect of all this on the income distribution is offset by a combination of two other factors. One is earlier retirement—only 24 percent of men aged 65 and over were in the labor force in 1972 compared with 46 percent in 1950 (U.S. Dept. of Labor). The other is the increased tendency of adults at all ages to head their own households.[1] Young people move out of the parental household sooner than they used to, old people are less likely to live with their children, and women—especially black women—are more likely to be family heads than they were a couple of decades ago. This increase in units, often at low-income levels, has made the distribution of income less equal than it would otherwise have been even though it doubtless reflects an increase in economic well-being. Rising incomes, including transfers, have enabled Americans to increase their consumption of a luxury good—the luxury of living apart from their relatives.

If one looks at the position of blacks in the income distribution the picture is a bit confusing. Since the early 1960's the ratio of black to white median earnings has risen somewhat for males and rather spectacularly for females.[2] The ratio of black to white family income, however, rose in the 1960's but has since declined (U.S. Bureau of the Census 1974). It is hard to see how these statements could both be true unless one remembers two other facts—that more black families are now headed by women and that a declining proportion of black men of all ages are in the labor force.

These various statistics reveal clearly that more is happening to the distribution of income than the constant size distribution would indicate—equalizing and unequalizing forces are cancelling each other out, although there is no obvious reason why they should continue to do so. The statistics also reveal something discouraging to economists—some of the most important influences on the size distribution of income are factors to which economists have given little attention. We do have some theory about the distribution of full-time male earnings, to which I will return presently, but we do not have much to say about family income. That depends on the groupings in which people choose to live (a subject that economists have always left entirely to God and the sociologists), the propensity of various family members to work (a subject that has evoked only a little interest from economists), the actions of the government, and the interactions of all these factors.

II. What Would Be Better?

Next we come to the question of norms or goals. What do economists have to say about the optimum distribution of income? Or at the very least, can we say anything about what would be better than the distribution that now obtains?

In a truly amazing act of self-denial, economists of the past generation have taken themselves out of the theoretical-philosophical discussion of how income ought to be distributed. Since they abandoned the notion that interpersonal comparisons of utility were possible and rejected the commonsense assertion that taking a dollar from a rich man and giving it to a poor man generally enhances the total welfare, they have not only stayed out of the argument, but devoted some of their most ingenious intellectual efforts to explaining to each other why they had so little to say.

---

[1] See U.S. Bureau of the Census, *U.S. Census of the Population, 1950,* "Marital Status"; *U.S. Census of the Population, 1960,* "Persons by Family Characteristics"; and *U.S. Census of the Population, 1970,* "Persons by Family Characteristics."

[2] See U.S. Bureau of the Census, *Current Population Reports,* "Consumer Income," various issues.

My own gut reaction is that the commonsense notion is correct—taking a dollar or a thousand dollars from a millionaire and giving it to a sharecropper with three hungry children *does* enhance total wellbeing. The interesting question is not whether this extreme proposition is true or not, but how far to carry it. The fact that members of our profession in the last decade have put hundreds of thousands of manhours into studying the very poor and designing policies to assist them attests to the fact that my gut reaction is widely shared, if not theoretically defensible. We are all pretty sure that raising the bottom of the income distribution enhances total welfare; we just aren't too sure what we think about redistribution in the middle.

The theoretically sanctioned position of the economists, however, biased their efforts away from redistribution and toward concern with economic growth. The bias is not necessarily detrimental to the cause of improving the share of the poor: it is probably easier to obtain political support for redistribution within a rapidly growing total than within a stagnant one, which may explain why there was so much more apparent support for helping the poor in the mid-1960's than there is now.

The one thing economists did feel that they could talk about without intellectual embarrassment was the tradeoff between equality and efficiency. One part of this argument involved the classical defense of the efficiency of paying all workers their marginal products, although everyone agreed it was not always possible to do this; another involved the labor supply effects of alternative tax rates, both positive and negative. The last question was the most relevant to actual policy debate since, except for minimum wages, the political decision makers seemed ill disposed to interfere with wage determination in an effort to equalize, but amenable to progressive taxes and income-tested transfers. Perhaps this was because economists were pushing in this direction. In any case, considerable effort has gone into estimating the possible labor supply costs of equalizing through taxes and transfers, but it seems only fair to say that the jury is still out.

There is one goal with which economists and a lot of other people have felt far more comfortable than they have felt with the goal of redistributing income in the present, namely, the goal of equalizing opportunity to earn income in the future. As long as equalizing opportunity was identified with lowering barriers to entry, such as racial or sexual barriers to education and training or to credit and job markets, or even when it was identified with equalizing productivity-enhancing public expenditures, such as expenditures for education or public health, economists and others felt they had something that was at least intuitively defensible. First, the current resource costs often appeared to be small. Letting blacks into unions or women into law school did not require any significant reallocation of current resources, although equalizing public expenditures often did. Second, the losers were not giving up income they had, only their expectation of future income gained by an unfairly advantageous starting position. Third, and most important, equalizing opportunity seemed likely to increase aggregate income, rather than reducing it. Conventional economic theory suggested that redistributing current income would reduce the size of the total—if one did it by paying people something other than their marginal product, there would be misallocations, and if one did it by progressive taxes and transfers, there might be less labor supplied—although persuasive empirical evidence to support the theory was lacking. It was not hard to show theoretically, however, that equalizing opportunity, by giving naturally productive people a chance rather than a handicap, might actually increase total output. Hence, equalizing opportunity to earn income, like free trade, was something the preponderance of the profession unabashedly viewed as a good thing. It was not quite a free lunch, but it came close.

Unfortunately, however, further thought and empirical research, much of it by noneconomists, has taken the almost free lunch off the table. It is now evident that lowering artificial barriers and equalizing public expenditures for human investment (for example, education expenditures) make relatively trivial contributions to equalizing opportunity to earn income. The family, it turns out, is an enormously powerful influence on individual capacity to perform successfully in school and in the job market (James S. Coleman et al.). One cannot discuss how far society ought to go in using public resources to compensate differences without facing the necessity from which economists are so eager to escape—that of balancing the welfare of the taxpayer and the beneficiary and, indeed, of trading the resources of this generation for more equal opportunities in the next.

At this point the economists are tempted to leave the field to the moral philosophers with the instruction: you guys tell us what ought to be done about equalizing incomes or opportunities and then we will help you do it. But unfortunately, there is no escape. Probably the most ambitious recent attempt by a moral philosopher to evolve a set of rules for economic justice is the widely discussed work of John Rawls. Rawls suggests that the way to decide what is fair is to think about what rules people would choose for a society in which they knew they were going to have to live, but had no idea what their social or economic status would be. He asserts, offering no empirical evidence, that people in this circumstance would be absolutely averse to risk. Taking no chances, they would agree on two fundamental rules. The first is that certain basic rights are to be distributed absolutely evenly and cannot be bartered away, either for individual or social benefits. The second has two parts—that income differences are tolerable only when they benefit everyone, including the least advantaged, and that advantageous positions are to be passed out on the basis of achievement with everyone having an equal chance at them.

These rules are appealing, but they do not get us any farther down the road to policy choices than the economists' agnosticism. In the first place someone has to decide what are the basic rights to which everyone has equal claim. If one includes what Arthur Okun has called "resource-using rights," such as the right to a minimum income or a decent house or access to medical care, then one has moved a long way toward income equalization, perhaps at such cost to the total product that the least advantaged are worse off (see Okun). If one defines basic rights narrowly, then the second proposition is troublesome. Deciding which inequalities are beneficial to the least advantaged is an awesome task for empirical research. At the moment, for example, the trickle-down school of fiscal policy is suggesting that the way to stimulate the economy is to lower taxes on business investment and capital gains, an apparent increase in inequality that is supposed to benefit the least advantaged by stimulating the demand for labor. Whether this school is in fact right that the least advantaged would benefit is an empirical, not a theoretical question. Moreover, as Coleman has pointed out, Rawls's endorsement of equality of opportunity is either trivial or involves very difficult decisions about what proportion of the national product should be devoted to overcoming the influence of the family on income-earning capacity and, indeed, about the extent to which the family should be perpetuated as a socializing force if it reduces equality of opportunity.

In my own view, discussions of optimum distributions of income or opportunity are fascinating intellectual parlor games unlikely to make any contribution to the policy debate on income shares. Economists who want to make themselves useful would be better advised to put their effort into defining some real policy alternatives, estimating their costs and effects and explaining what they are talking about to the public and its political representatives so that the political process, for all its faults, can at least operate with more knowledge of what is possible than it has at present.

It should be noted that the revealed preferences of the American public with respect to income-equalizing policies are a mixed bag, judging from the current array of federal activities that directly affect the distribution of income. The preponderance of federal cash transfers goes into programs whose effect is to even out income inequality over the life cycle (e.g., social security and other retirement programs) or to reduce transitory income inequality due to inadequate aggregate demand for labor. Few resources are devoted to offsetting differences in earning capacity as such. On the tax side, popular tolerance for the regressive payroll tax and lack of support for income tax reforms that would clearly benefit the majority of taxpayers suggest either that the political process is a poor reflection of majority preferences, or that no one understands what the choices are, or both. It is in the solution of this latter problem—elucidating the options—that economists seem to have the most to contribute. Before one can do that, however, one needs a workable theory of how income in fact gets distributed.

III. Why Things Are as They Are

It seems only reasonable that those concerned with the size distribution of income should ask economists why they think the distribution is so unequal.[3] Why do so many have so little while a few have so much?

Economists have made some valiant efforts to answer this question. Vilfredo Pareto even thought he had discovered a natural law that accounted for the shape of income distributions in a wide variety of places in various time periods. Pareto was concerned with the distribution of total income, but most of the other theorists who have tackled the problem have confined their attention to the distribution of earnings, especially full-time male earnings. Indeed, it is something of a paradox that what economists think of as "income distribution theory" relates to the distribution of earnings of fully employed males, while what they think of as "income distribution policy" means almost everything else.

Over the years various theorists have offered explanations of the puzzling fact that the abilities of individuals, whether physical or intellectual, are distributed normally while the earnings distribution is more nearly normal in the logs. This observation suggested that some multiplicative factor related ability and earnings; for example, that several different kinds of abilities determine earnings and that they are multiplicative in their effects, or that individual earnings, initially proportional to some index of ability, are subject to a series of random proportional shocks. These theories were intriguing, but devoid of any policy significance. Indeed, only within the last fifteen years has economics produced a theory—the human capital theory—that both offers a credible explanation of the shape of the earnings distribution and some potentially testable hypotheses about how one might intervene to change that distribution.

---

[3] For a good general review of income distribution theory, see Martin Bronfenbrenner and Jacob Mincer (Mar. 1970).

Human capital theory was appealing to scholars not only because it offered hope of accounting for the shape of the earnings distribution, but also because it accounted for part of the unexplained variation in earnings among individuals, regions, and subgroups in the population.[4] It even answered some questions that no one had thought needed asking, like why people tend to get their education when they are young.

But an even stronger appeal of the human capital approach was to people with an interest in policy and a predisposition to the belief that education was a good thing and ought to be better funded. (Economists tend to fall in this category, not only because they have invested so much in their own education, but because they so frequently earn their living educating the young.)

First, of course, the human capital approach provided a rationale for education spending in a growth-oriented society. The exact calculations were not important—no one cared much whether social rates of return on additional education were 5 percent or 15 percent as long as they seemed to be positive. If one was proeducation, one could imagine all manner of external benefits of education—from reduction of crime to more intelligent behavior in the voting booth—that had not been counted in the rates of return. The point was that education could be thought of as an investment and therefore a worthy use of resources, not a wasteful frivolity that consumers wanted only for their own enjoyment or for impressing their neighbors. This basic idea may have done as much as Sputnik to convince legislators of the 1950's and 1960's that increasing education spending (more than was dictated by population increases alone) was in the public interest.

Second, the human capital approach suggested that subsidies for education and training could be used to alter the income distribution in one of two distinct ways: (1) raising the relative position in the income distribution of people whose parents were near the low end; and (2) narrowing income differentials in the coming generation compared with what they would otherwise have been.

It is important to be clear that these are not the same thing. Improving the relative position of some small fraction of the next generation (i.e., their own children) is what motivates parents who scrimp and save to move into a neighborhood where the schools are better or to take a second job to send the kids to college. Parents are not trying to narrow income differentials among the next generation; on the contrary, they think large differences between the incomes of the well educated and the poorly educated are just fine as long as their own kids make it into one of the top groups. The motivation behind the education and training components of the 1960's war on poverty appears to have been similar to that of parents seeking to improve the chances of their kids. The notion was that additional public resources could be concentrated on a fairly small number of young people (or even adult workers) who would otherwise be likely to have low incomes, and that this additional investment would improve the relative position of the recipients. It might, of course, be more efficient to improve their relative position by giving them money, but the education route had more political sex appeal.

---

[4] See, for example, Gary S. Becker (both references), Mincer, and Barry R. Chiswick.

Success in this endeavor requires: (1) that the additional resources devoted to the education of the disadvantaged actually do some good, in the sense that the students or trainees actually increase their skills or acquire valuable credentials, and (2) that there not be so many people with the new skills or credentials that the wages they command fall and the income advantage diminishes.

Alternatively, however, the public policy objective might actually be to narrow disparities in the distribution of income among the next generation. Human capital theory suggests that one way to do this—again not necessarily the most efficient way—is to increase the proportion of people attaining higher levels of education and training. Other things being equal, this would increase the competition for jobs with high education or skill requirements and lower the wages those jobs command. At the same time, wages of jobs requiring less skill and training would tend to rise, and disparities in income among education and skill levels would be reduced.

Such allegations are hard to prove, but I suspect that narrowing disparities in income was *not* among the significant motivations for the major expansion in public subsidies for higher education that occurred in the last fifteen years nor for the education and training programs of the war on poverty. The proponents of these programs were focused on giving all young people including the children of the poor a chance to improve their expected income, *not* on reducing inequality per se. They hoped, in fact, that the income differentials between education groups would remain large rather than erode under the impact of the policies. There would then be no losers, only gainers.

One of the minor economic mysteries of the 1960's was that these hopes were not disappointed. Despite substantial increases in high school graduation rates and in the ratio of college to noncollege workers, income differences did not narrow at all. In 1960, for example, men aged 35–44 with four years of college had 1.91 times the median earnings of those with only eight years of schooling; in 1970 the comparable ratio was 1.92—another one of those "stuck" statistics.[5]

At the time an explanation seemed in order and several have been offered. First, technology may be changing in such a way that the demand for employees with the skills acquired in education is shifting upward at about the same rate as the supply. Second, labor markets may not actually work in the neoclassical way that human capital theorists have assumed they do. Alternate theories of labor market functioning abound at the moment and several have been used to explain why income differentials among income groups did not narrow in the 1960's. The most drastic explanation simply rejects the human capital theorists' contention that education enhances productivity, and suggests that the only reason that education is correlated with income is that the combination of ability, motivation, and personal habits that it takes to succeed in education happens to be the same combination that it takes to be a productive worker. If one takes this view, then changes in the supply of people with various amounts of education are simply irrelevant to the distribution of earnings and there is no reason to expect one to predict the other.

An intermediate explanation may be that those aspects of education that count in the labor market are not actually being equalized as much as the data on years of schooling would suggest. There may be a basic number of years of schooling that society expects everyone to have and that counts for nothing in the labor market because all but the subnormal have it. Much of the shift in education in recent years can be construed as a shifting upward of the base level, rather than a change in the proportions of workers having significant amounts of education beyond the base level.

---

[5] See U.S. Bureau of the Census, "Educational Attainment," 1963, and "Educational Attainment," 1973.

Whatever the merits of these hypotheses, more recent data suggest that the decline in the relative earnings of recent college graduates, expected in the 1960's, is actually occurring in the 1970's and that the delay may have been attributable to the fact that such a large fraction of the college graduates of the 1960's flowed into graduate and professional schools and did not hit the labor market immediately (Richard B. Freeman). It is too soon to tell, but if the drop in relative earnings of highly trained people does continue, it will be somewhat harder to use education as a tool for enhancing social mobility. It will be good news, however, for those who see education as a way of narrowing disparities in income.

Even if one accepts human capital theory and conventional views of labor market operation as, so far, the best explanation of the earnings distribution that we have, one cannot make a strong case for relying on educational investment as a primary tool for changing the income distribution. At best the effects of education are slow in appearing, the proportion of the variance in income explained by education is not large, and firm empirical evidence is weak that increased expenditure for education of particular students actually increases their future income. Alternate views of the labor market and alternate explanations of the correlation between income and education—such as the queuing, screening, and dual labor market models—offer even less support for education as a tool for increasing income equality.[6]

IV. What Can We Do About It?

The pay-dirt question, of course, is what policies might change the distribution of income—presumably in the direction of greater equality, since no one is likely to advocate less equality as an explicit objective. How would such policies work? What would they cost?

There has been a major accumulation of useful knowledge in this area in the last ten or fifteen years and economists have good reason to be proud of their contributions. They have put tremendous effort into the study of redistributional policies and have learned a great deal that ought both to improve politicians' abilities to make informed choices and the workability of any programs that are chosen. It is not economists' fault that the real world is so complicated and that much of what has been achieved is an elaborate documentation of the fact that there are no quick and easy solutions to problems that have been around for a long time.

It can be argued, of course, that it is better not to know so much, because knowledge of the complexity of the problem paralyzes action. But the history of the 1960's teaches the opposite lesson: naive hopes and hastily designed programs can produce a disillusionment with public intervention in general that is itself paralyzing.

So let us suppose that there is a new High Wizard in Washington—you may identify him as a President or a Congress or both—who has a landslide election behind him and an interest in fairness and in improving the lot and the future chances of those below the middle of the economic ladder. The Wizard calls his Trusty Economic Adviser (TA) and says: You and your colleagues have been working on this problem for a long time and I want to know what you have learned. What policy choices do we really have? Trusty Adviser, of course, starts by saying that he needs another ten years to work on the problem and a lot more money for research, but the Wizard won't buy that—he wants to know what is known *now.* OK, says TA, but first, tell me what you want to happen. Three things, replies the Wizard. First, I'd like the very poor to be better off—closer to the average. Second, it doesn't seem fair to me that there should be such concentration of income in the hands of the families at the top. And third, I think there ought to be more chance for people at the bottom to move up or at least to see their children move ahead. It's bad when people get stuck at the same level with no hope of improving their position. You want to do all three? asks TA. I'd at least like to make some progress, says the Wizard, but of course I have some constraints. The people who elected me are not socialists or anything. So just tell me what's possible without making the government very much bigger than it is now. What could be done with taxes and government programs? Let's start with education.

---

[6] See, for example, Kenneth J. Arrow and Lester C. Thurow and Robert E. B. Lucas.

Education may be a good thing to spend more resources on, says the TA, and there certainly won't be much upward mobility unless low-income children have access to education. But I have to warn you that increasing education spending is probably a slow and relatively ineffective way to change the income distribution. You could, of course, try spending substantially larger sums on the education of children from families in the lower part of the distribution. You could reach them earlier through preschool programs; you could buy them more teachers, better facilities, and special "compensatory" programs in elementary and secondary school. All this would make their lives a bit less grim, and in theory this would improve their performance in school and increase their chances of earning more money later on.

Why do you say "in theory"? interjects the Wizard. Because in practice no one knows how to do this. One thing that makes it difficult is that your national government does not control how local schools spend money, but the main problem is that no one knows what to tell the schools to do. Statistical studies do not prove that higher spending for schools is associated with better performance of children—as long as the children's home background is held constant—and evaluations of special new educational programs have not yet shown convincingly that any of them lead to permanent increases in the school performance of low-income children or any other children. Of course, a bigger research effort on teaching and learning might lead to a breakthrough that would make education spending more effective. Such a breakthrough might help low-income children more than others—the way control of contagious diseases helped the poor more than the rich—but there is also the risk that it might be of most help to those who need it least.

Are you saying, asks the puzzled Wizard, that spending more per child in elementary and secondary school is a waste of money? Not at all, replies TA. I'm just saying that economists cannot prove that the additional spending will raise children's test scores or incomes. But we can't prove that increments in most public expenditures have measurable effects especially on income. Good education is something most people want for themselves and their children. You politicians have to figure out how much they want it and how to distribute it fairly and I'm afraid you aren't going to get much help from economists.

But, says the persistent Wizard, how

about encouraging students from low-income families to stay in school longer, especially making it financially possible for them to go to college? We're on firmer ground here, admits TA. Making the college option available to students from all income levels is bound to increase mobility from one generation to the next. If a lot more students go on to higher levels of education, there may be more competition for high status jobs and the distribution of income may even become more equal. Of course, you may have to deal with some disappointed people. Some of those who thought a college education was going to guarantee them a professional or managerial job and a high income may feel they were misled. Also it is my duty as an economist to point out that the education purveyed by our colleges and universities is expensive and if your objectives are to raise the relative income of the poor or to narrow income differentials (not just to facilitate upward mobility in status or occupation) it might be cheaper to do it by taxing higher income people and supplementing the incomes of those who earn less.

Ah yes, says the Wizard, you economists developed something called a negative income tax to solve this problem. Should I try that?

You certainly ought to consider it, replies TA. A lot of economists got excited about the negative income tax in the early 1960's because it seemed to be such a clean, elegant solution to several problems at once. It would put a floor under everyone's income—indeed, the floor could bear some relation to average income, as you suggested—without destroying incentives to work. Combined with reform of the positive tax system, to raise average effective tax rates on high-income people, it could not only raise the share of those at the bottom of the income distribution, but could also reduce the concentration of income among those at the top. In the last decade we economists have done a lot of hard practical work on this general idea. Besides theoretical and statistical studies of the usual sort, we have designed and analyzed actual experiments and have helped lay out detailed plans for turning the government's welfare system into something resembling a negative income tax or having the tax authorities take on these new responsibilities.

That's nice, says the Wizard, a little impatiently, but what have you learned from all of this that will help me decide what to do? I was coming to that, says TA. First, the experiments proved that a negative income tax was not just a crackpot idea; it was actually possible to administer one. Moreover, male family heads did not quit working just because they were getting the payments, although some of their wives did. We still don't know, of course, how the results of a real long-term national program would differ from those of a short-term local experiment. Second, all the work on legislative proposals revealed that it was very difficult and expensive to use a negative income tax both to supplement the wages of low earners and to support families with no earners at all; that it was hard to start a national program when wage levels and public attitudes in various parts of the country were so different; and that a lot of complex tangles have to be straightened out before a negative income tax can be made to mesh with the positive tax system and other existing government activities.

Are you telling me, asks the Wizard, that economists don't favor a negative income tax anymore? No, no, replies TA patiently, lots of them, including economists of very different political persuasions, still think that a negative income tax, plus reform and simplification of the positive tax system, is the best approach to reducing the concentration of income and improving the position of the poor. It's just that we now realize that a negative income tax is no easy panacea, and we are increasingly skeptical of our ability to explain it to politicians and the public and persuade them it is a good idea. Some of us tried that in a recent presidential campaign and it didn't work out too well. Hence, many of us are leaning to more eclectic solutions.

Tell me what you mean by that, demands the Wizard. Well, a lot of economists used to be purists about redistributing income in cash so that recipients of the benefits could choose freely how to spend them—presumably buying what they needed most. But some of us have realized that the public may be more willing to pay taxes to ensure that everyone has the basic essentials, such as food, housing, and medical care, than to hand over cash to people whose spending priorities may differ from their own (Thurow and James Tobin). So you may be more successful with your redistribution program if it features health insurance and housing assistance, rather than just a negative income tax. Of course, there are problems with this too. If people are eligible for a lot of different benefits, each of which is related to their income, they may in effect be facing very high marginal tax rates on their income. There is also a problem of deciding what form assistance should take. Most economists believe in markets so they usually favor giving the equivalent of a voucher to the consumer and letting him choose among suppliers; but, of course, suppliers like it better when the subsidy goes directly to them.

Actually, if you are serious about your objectives, you might try all these policies at once: education, negative income tax and positive tax reform, plus greater efforts to ensure everyone such essentials as medical care. Is that a recommendation? asks the Wizard. Oh, I don't make recommendations, replies TA, I just tell you what the choices are.

This facetious-sounding conversation comes close to mirroring, as I perceive it, what the TA's have to tell the Wizards right now. Of course, the contributors of advice include only those who hold some hope for change within the system and do not view all government actions as part of a conspiracy of the few to oppress the many. Moreover, at the moment most of the Wizards are not listening.

Clearly, economists have done a lot to make the policy discussion more informed and constructive than it was ten or even five years ago. We may have contributed to the loss of innocence, but we have also accumulated some practical knowledge that can be used to effect change if a political Wizard with a passion for fairness and a will to change the income distribution asks for advice.

Actually, however, Wizards don't ask—they generally have to be persuaded that a problem exists whose solution would be popular, at least with substantial numbers of the electorate, and, more important, that change is possible. Once that happens they may even pick up a half-formed policy proposal and run with it too hard and too fast. Although some economists may bemoan the lack of influence of our breed, my own view is that in the income distribution area the political world grabbed some economic hypotheses—such as human investment as a cure for low earnings or negative income tax as a solution to income inadequacy—before the economists were quite ready to turn them into proposed laws. The result was disillusionment that turned people away from the objectives, rather than causing them to renew their efforts to find solutions. If the new eclecticism among economists means, among other things, a new willingness to work hard on the details and possible limitations of policy proposals, it may presage an end to the enthusiasm-disillusionment cycle of recent years and some real, albeit incremental, movement in the direction of a more equal income distribution.

THE ECONOMICS OF LABOR: AN ASSESSMENT OF RECENT RESEARCH

The Challenge of Dual and Radical Theories of the Labor Market to Orthodox Theory

By GLEN G. CAIN*

Ideally, a paper that attempts to evaluate a challenge to established theory should accomplish the following objectives:

1. Present the theoretical substance of the challenging theory, which is here called the dual and radical theories, and indicate how it differs from the existing theory, which I will refer to as neoclassical or orthodox theory;
2. Point out the empirical implications of the new theories and explain their differences with the existing theory;
3. Assess the empirical basis for discriminating between the competing hypotheses or, if this is lacking, provide the theoretical or evidential counterarguments of the neoclassical response to the dual and radical challenge; and, finally,
4. Spell out the policy implications of the competing theories.

Meeting these objectives is an impossible task for a short paper. The space constraint is compounded by the fact that in my judgment the dual and radical theories are too varied, incomplete, and amorphous to present concisely. The strategy I adopt to describe these theories in the longer paper consists of, first, discussing their linkages to historical criticisms of classical and neoclassical theory; second, developing their empirical challenges to orthodox theory. Only the second part is emphasized below.

To establish the context of the challenge, let us begin with the observation of Leo Rogin (p. 13) that: "new systems (of economic doctrines) first emerge in the guise of arguments in the context of social reform." The dual and radical (or *D–R*, for short) theories began to emerge in the 1960's when the movement for social reform mainly involved the war on poverty and the drive for full participation in the economy by minority groups, including women. Dissatisfaction with the pace and progress of reform in these areas and dissatisfaction with the conventional analysis of the problems and their remedies have led to arguments within the economics profession, especially on the part of the younger labor economists.

Let me simply assert, without defending the proposition as I do in the longer paper, that the neoclassical school does dominate the profession today, even within labor economics where, as I mention below, it was not dominant during the 1940's and 1950's. I will also assert that neoclassical theory means, in general: (1) the theory of the demand for labor contained in the marginal productivity theory and the associated research on production functions; and (2) the theory of labor supply consisting mainly of models involving the labor/leisure choice and human capital investments.

---

* Department of economics and Institute for Research on Poverty, University of Wisconsin. This is an abbreviated version of a longer paper, which is available from the Institute for Research on Poverty, University of Wisconsin, Madison, Wisconsin 53706. The longer version contains a bibliography, which is omitted here. I am indebted to a number of people at the U.S. Department of Labor, especially Fred Siskind, and at the Institute for Research on Poverty for their support. They are not responsible for errors, nor do they necessarily agree with the interpretations expressed in the report. I am grateful to Marc P. Freiman for his extensive assistance.

Theory, however, operates on at least two levels. As a framework for analysis, neoclassical theory implies a set of methods and techniques—for example, marginal analysis of behavioral relations in which income and prices are key variables. Second, as a body of substantive behavioral propositions, neoclassical theory implies a large number of qualitative predictions and quantitative estimates of parameters about behavioral relationships. The dual and radical critics attack both the methodology and the collection of predictions and substantive hypotheses. Those attacks inevitably spill over into policy disputes.

I. A Classification of Issues Raised in the Dual and Radical Literature

Out of this background we can discern three types of issues raised in the *D–R* literature: first, criticisms of the outcomes and processes taking place in the labor market; second, a rejection of the existing theories and methods that have purported to explain the operations of the labor market; and third, a call for new and more radical policies.

A. Empirical Generalizations

It is useful to distinguish between two types of facts which contribute to controversy. The first are those that indicate some sort of hardship or distress, such as high levels of unemployment and poverty. The facts about these problems may not be in dispute. The second type of descriptive empirical findings consists of unresolved and inadequately treated problems, which may or may not concern matters of hardship. The empirical challenges raised by the *D–R* spokesmen usually concern the overlap—empirical anomalies about pressing social problems. I will list eight problem areas, some of which have subtopics.

1. As noted above, the most important problem motivating the *D–R* economists was the persistence of poverty in conjunction with the affluence of society and the scope of governmental efforts to eradicate poverty. This problem is too broad, however, and we must turn to its more particular aspects, listed below as items 2 through 7.

2. One such problem is the failure of education and training programs which, according to the *D–R* critics, demonstrate a failure of the human capital models and call into question the conventional acceptance of a causal connection between formal education and labor productivity. I comment on the alleged failure of social action programs below. Concerning the general education-productivity relation, my judgment is that its empirical support is shakiest regarding the intensive margin of educational investment—that is, the effect of more educational resources, holding years of schooling constant. There is, I believe, ample empirical support for a payoff at the extensive margin—that is, positive returns to more years of schooling. The orthodox interpretation of this empirical relation is, however, called into question by the next point.

3. Employers used educational and training indicators merely as screening devices—either to discriminate on grounds other than productivity, or to serve as a proxy for potential productivity that is not directly related to what was actually

learned in the educational institution. The latter purpose, it should be noted, redefines the investment nature of education as "information"; it does not deny that any investment takes place. However, a denial of either the real productivity of education or of the potency of the informational content of educational attainments does challenge the orthodox assumptions about rational behavior and/or about the degree of competitiveness in the economy.

4. The income distribution remains as unequal now as it did twenty years ago, in spite of the decrease in the variance of educational attainments in the adult population.

5. A collection of problems concern the large and persistent differentials in earnings between white and black males and between males and females. These challenge neoclassical models of discrimination which predict a withering away of the differential under conditions of competition. Several more specific empirical puzzles in connection with labor market discrimination may be listed: the decline in black male labor-force participation rates relative to white males in recent years; the near-constant ratio of black-to-white earnings from 1950 to 1966 or so; the long-standing empirical relation showing a decline in the ratio of black-to-white male income with higher educational attainment; the flat wage-earnings profile of black males and all females relative to white males as revealed by cross-section surveys; and, finally, the stagnant trend in earnings and occupational attainments of women relative to men during recent years. Associated with this trend is the slower growth in female educational attainment compared with men from 1940 to 1973, despite the sharp increase in labor-force participation of women during this period.

6. The roles of monopolies, unions, and other sources of protected labor markets have been a long-standing problem area. The *D–R* spokesmen imply that these are so pervasive as to make untenable the empirical work of orthodox labor economists, which usually assumes competition.

7. Another area is the role of psychological variables measuring the attitudes and motivations of workers. Conventional economists have customarily viewed tastes for work as exogenous and as one of the (unexplored) causal variables explaining employment, earnings, and occupational achievements. The challenge of the *D–R* theories lies in their claim that tastes are endogenous and a result of one's labor market achievements.

8. Alienation among American workers is the final listed problem. If we assume as true the disputed contention that alienation and dissatisfaction among *U.S.* workers are widespread and increasing, the challenge to orthodox theory may be stated as follows: Why has the market not responded to the workers' tastes and preferences either by a redesign of jobs and upgrading of working conditions or simply by appropriate wage rate compensations?

The foregoing list of empirical generalizations about outcomes and operations of the labor market covers, I believe, the main bill of particulars in the *D–R* indictment. Let us now comment briefly on their theories of how the labor market operates.

B. Alternative Theories

In the absence of any single, well-articulated theory in the dual and radical literature, I will mention three versions that veer progressively further from orthodox theory.

Perhaps closest to the orthodox is Lester C. Thurow's job competition theory, which is contrasted with the orthodox wage competition theory (Thurow and Thurow and R. E. B. Lucas). Its main elements are: (1) the number and type of job slots are technologically determined; (2) the workers' skills (i.e., human capital) and wage offers are nearly irrelevant in determining the number and type of job positions actually filled; (3) queues of workers for jobs offered at fixed wages constitute the supply of labor, and the employer's assessment of the workers' trainability and adaptability determines which workers are hired; and (4) fluctuations in macro policies will lead to changes in the demand for labor and thus to changes in the lengths of the queues. The theory emphasizes the within-firm (or internal) labor market as the locus of decisions about allocations, promotions, and on-the-job training—all of which are relatively insulated from the external labor market. In many respects this theory is similar to the dual market theory.

The dual labor market theory of Peter B. Doeringer and Michael J. Piore depicts a labor market divided into primary and secondary markets. The former contains the jobs in large or profitable firms and the unionized jobs. These jobs are higher paying, offer promotion possibilities, better working conditions, and greater stability. The secondary labor market contains the low-paying jobs which are held by workers who are discriminated against and who have unstable working patterns. The discussion of this duality tends to be merely descriptive, and perhaps descriptive only of polar cases. Many of the theoretical ideas are similar to the job competition theory; namely, the demand-determined allocation of jobs and the downgrading of human capital characteristics as determinants of wage levels. In addition, considerable attention is given to the role of employer discrimination. Also, the worker's attitudes, motivations, and work habits are viewed as mutually reinforcing determinants of a worker's assignment (and confinement) to the primary or secondary sector of the labor market.

The third version of a labor market theory is referred to variously as radical, segmented, and stratified theory (see David M. Gordon). It expresses a more explicit critique of capitalism, acknowledges its ties to Marxian dialectical analysis, and emphasizes class conflicts. The dual labor market idea is sometimes expressed in terms of an analogy with an underdeveloped economy or even with a colony which is exploited by the primary economy. Radical theories are also similar to dual market theories in drawing upon sociological analysis of institutional change and power relations and upon psychological analyses of the determination of workers' and employers' attitudes, preferences, and motivations.

The expositions of these theories are stronger in their criticisms of neoclassical theory than they are in advancing a coherent replacement. Criticism of classical and neoclassical theory has a long and, in many instances, a distinguished history, so casting the *D–R* writings in this mold can be complimentary. To the extent that the issues raised have appeared before (even though in different terms) and remain unresolved, the challenge is all the more compelling. On the other hand, if the issues have been satisfactorily answered before, the challenge is less compelling. In either case an historical perspective can be informative.

Space limitations prohibit this development, but mention should be made of the similarities of the dual and segmented market theories to the Mill-Cairnes theory of noncompeting groups and to several ideas of the neoinstitutionalist group of labor economists who dominated their field in the 1940's and 1950's. Of this latter group, John Dunlop had written of internal labor markets, and Clark Kerr had advanced the idea of labor market segmentation in his famous article about the "balkanization" of labor markets.

C. Policy Implications of the D–R Theories

One set of policies advocated in the *D–R* literature concentrates on the labor market; another deals with the larger issues of power relationships and nonlabor market institutions in society. The first set of policies is most clearly distinguished by a focus on the demand side of the labor market. Specifically, public employment, wage subsidy, and antidiscrimination programs are stressed. Intervention on the supply side of the market, particularly the human capital investment programs of education, training, and job search assistance, is deemphasized if not rejected.

A second set of policies advocated by the radical economists is less specific. These include prelabor market conditioning of the consciousness of people, perhaps calling for a reorganization of schools and other community institutions. They may also advocate that workers gain a more dominant role in governing their work—thereby combating alienation and partly achieving a general realignment of political power.

II. The Modern Neoclassical Response to the D–R Challenges

Again, space limitations prohibit much more than a listing of comments. I have divided these into a methodological theoretical section and an empirical theoretical section.

A. Methodological and Theoretical Issues

The defense of neoclassical research includes the following points: (1) adherence to the view that positive economic analysis is separable from normative analysis and, in particular, a denial that neoclassical models presume a regime of harmony rather than conflict among various economic groups in society; (2) belief in the utility of building models which assume either that tastes and institutions are fixed and/or that these variables may be omitted from the model without biasing the estimated economic parameters, such as price and income effects; and (3) finally, a denial that neoclassical theories of wages and employment rest solely, as *D–R* spokesmen often claim, on the marginal productivity theory.

B. Empirical and Theoretical Issues

What follows is a listing of five topics which provide an arena for debate. My main message is that more empirical evidence is needed, but that the *D–R* position is generally weaker than the neoclassical position on a priori grounds.

1. Two questions arise about the ***occupational structure.*** Does a static snapshot reveal a duality, and if so, what metric of occupational status produces this bimodality?[1] Another question concerns occupational mobility. Over time, are workers with a definable premarket characteristic confined to one segment of the occupational spectrum? There is little evidence on this question.

2. The neoclassical theories of ***discrimination*** have developed along three lines: competitive models which predict a long-run disappearance of wage (or job) discrimination; noncompetitive theories, which are downplayed on grounds that monopoly and monopsony are not empirically important; and competitive-statistical models, which in my opinion place too much of a burden on informational unreliability to rationalize the extent of discrimination that we observe. In their empirical work, neoclassical economists have stressed prelabor market sources of the disadvantages for both blacks and

---

[1] Occupational segmentation associated with sex and race groups is treated separately below under the topic of discrimination. Presumably, the segmentation of teenagers and the aged could be set aside as well, since there is no puzzle about their occupational differences compared with prime age workers.

women, thus attempting to reduce the burden of explaining market discrimination. These approaches, taken in total and despite their defects, appear more persuasive to me than the *D–R* models of exploitation, employer strategies of dividing and conquering their work force, or self-perpetuating and vicious circle theories.

3. Two points may be made in response to the *D–R* emphasis on *unemployment and job instability*. One is that if the human capital models explain individual workers' low wages, then they are in principle capable of explaining other undesirable forms of job rewards, such as instability. Second, a more direct analysis of job instability is addressed in the job search literature of neoclassical economists, which also attempts to reconcile macro and micro theories of unemployment. This effort is just beginning, however, and there are some theoretical and empirical gaps. (See James Tobin.)

4. The question that separates the *D–R* from the neoclassical views of the issue of *wage rigidities and protected labor markets* is almost entirely one of the empirical frequency, duration, and importance of these market imperfections. The neoclassical economists have, in fact, used these ideas in studying underdeveloped economies and in analyzing minimum wage laws and the effects of unions on wages and employment in the *U.S.* economy.

5. The alleged *failure of training and educational programs* raises the messy problem of evaluating the evaluations of social action programs. I question whether a simple verdict of failure or success is justified. There is, however, one technical point about the statistical estimation of human capital models which has led to a misinterpretation by the *D–R* spokesmen. The allegation that human capital variables have small or zero effects on earnings of the lower strata of workers is often based on regression models in which the dependent variable is effectively truncated—consisting of predominantly low values. However, the regression coefficients of independent variables like years of schooling or training are clearly biased toward zero in these truncated regressions, so the pessimistic findings are partly artifactual.

III. Conclusion

My brief summary judgment of the *D–R* challenge is that it does not begin to offer a theory of the labor market that can replace neoclassical theory, despite our various degrees of dissatisfaction with the empirical corpus of that theory. The *D–R*'s theoretical and methodological criticisms of the neoclassical theory are not substantial and are often misguided; nevertheless, a tradition of criticism of orthodox economics is sustained and this is healthy. Neoclassical research can become terribly inbred and out of touch with policymakers or practical users of economic predictions. This danger is particularly acute because the standards for empirical verification are so weak.

The *D–R*'s theoretical contributions, which amount to modifications and additions to orthodox theory, are: (1) the ideas of the endogenous determination of attitudinal variables among workers; and (2) the institutional dimensions of internal labor markets—which enrich our understanding of the economics of bureaucratic organizations.

In the areas of empirical research and policy prescriptions, the dual and radical school represents an important voice. Although their research suffers, in my opinion, because it is not anchored to as tight and consistent a theory as neoclassical theory, this fault is compensated by their new ideas and their discovery of empirical anomalies in the orthodox paradigm.

Economic Analysis of Trade Unionism

By George E. Johnson*

The study of the behavior and effects of trade unions is not currently one of the major growth industries of the economics profession. For example, the average proportion of all articles in the *American Economic Review* (*AER*), *Journal of Political Economy* (*JPE*), and *Quarterly Journal of Economics* (*QJE*) dealing with questions concerning unionism, which seems a reasonable index of the degree to which economists at large consider the study of unionism to be interesting and important, has declined steadily for the past thirty years. In the 1940's, 9.2 percent of the articles in these journals dealt with union topics. This fell to 5.1 percent in the 1950's, further to 2.3 percent in the 1960's, and to just 0.4 percent during the first four years of the 1970's. Clearly, this index is not going to fall very much more.

It is not difficult to understand why the relative interest in trade unions has declined. First, the fraction of the civilian work force organized by unions has remained roughly constant at about 25 percent since the early 1950's, and with the exception of government employees, there appears to be little likelihood of a major increase in the extent of organization in the foreseeable future. Second, unionism in its present form has been quite secure since the early 1950's; its existence is not a serious matter of public policy as it was prior to that time. Hence, there is little call (i.e., no funding) for a judgment on the question of whether unionism is a good or bad thing. Third, there has been a great deal of activity with respect to policies concerning discrimination, antipoverty programs, income maintenance, and the like, and this has further diverted attention away from unionism. Indeed, the proportion of all articles in the *AER*, *JPE*, and *QJE* which deal with labor economics topics other than unionism increased from 4.8 percent in the 1950's to 7.4 percent in the 1960's and has reached 10.3 percent in the first part of the 1970's. Fourth, the earlier labor economics placed a strong emphasis on the examination of institutions in themselves rather than on their effect on economic variables, and its methodology was rather different from that of general economics. The resultant theory of wages and income distribution was not very satisfactory and, perhaps more importantly, could not be readily integrated into the mainstream of the discipline. Because of the development of human capital theory, we now have a much more satisfactory theory of income distribution, but the analysis of the effects of various institutional rigidities, unionism being one of the major ones, is not well developed. As D. Hamermesh (1973) suggested, it might be optimal for some of the resources presently devoted to the refinement of the new labor economics to be reallocated to a consideration of some of the problems considered by the old labor economics. As my survey of a subset of the latter will suggest, there remain a good number of questions which have not been resolved.

In the remainder of this paper I shall discuss—somewhat selectively—recent progress which has been made in answering three questions concerning the effects of trade unions. The space constraint has ruled out a similar discussion concerning behavioral questions, but it is worth noting that the problem of modeling trade union behavior has proved to be virtually intractable. This is because (1) there is no consensus on the goals of union activity (see W. N. Atherton) such as exists with respect to the firm or consumer and (2) the received pure theory of bargaining is devoid of operational content. The absence of a solid theoretical foundation has handicapped the economic analysis of trade unions and has surely contributed to its decline in relative attention.

---

* The University of Michigan.

I. Relative Wage Effects of Unionism

Regardless of what unions seek to accomplish or how they bargain with management, the question of how much more union members receive than comparable nonunion labor is both interesting and resolvable, and it has received a great deal of attention in the past few years. The stimulus to this recent research was the work of H. G. Lewis (1936b) in which the methodology of the topic was developed, all major previous studies were dissected and extended, and new sets of estimates were derived. Lewis' estimate of the proportionate wage advantage of union members over labor in the nonunion sector was 15 percent in the 1955–1958 period, but the estimate ranged from essentially zero in the late 1940's to 38 percent in the early 1930's,

The method of estimating the effect of unions on the relative wages of their members is upon first consideration fairly straightforward. In principle the wage rate for the ith worker (or the average wage for the ith industry or occupation) could be estimated by an equation of the form

$$(1) \qquad \log W_i = \beta U_i + \gamma X_i + \epsilon_i,$$

where W_i is the wage, U_i is a one-zero variable denoting union membership status (or the average extent of union membership for aggregate data), and X_i is a vector of all other variables besides unionism which influence wages (education, sex, race, experience and its square, geographic location, and the like), and ϵ_i is a random disturbance term. The estimated value of β provides an indication of the effect of unionism on relative wages. In particular, the proportionate wage advantage due to union membership, other things equal, is $\lambda = \exp(\beta) - 1$. The problem is to obtain the appropriate set of adjustment variables so that the estimator of β is unbiased. The early studies as well as Lewis' were based on data which did not permit much adjustment for other factors, but the development of micro data sets and computing machinery gave rise to a number of studies which could control more carefully for variations in (at least most of) the elements of X_i. L. Weiss used the 1960 Census 1/1000 tapes with industrywide unionization data and obtained results implying an average estimate of λ of about 20 percent for all male operatives and craftsmen in unregulated industries. F. Stafford employed Survey of Consumer Finances data for 1966, which had information on individual union membership status, and obtained estimates of λ of between 18 and 52 percent for all wage and salary workers. A. Throop used aggregate industry data and regressed wages on unionism, a skill index, and average city size of residence of the employees of each industry. His estimates of λ were 25 percent in 1950 and 30 percent in 1960.

The wide range of estimates of the union relative wage effect was consistent with Lewis' finding that λ varies over time and across industries. Thus, a number of studies attempted to disaggregate the data to obtain estimates of λ for various subsets of workers. In terms of equation (1), this means that U_i influences the dependent variable interactively with some of the elements of X_i. The Weiss study attempted to estimate the differential effect of unionism for different degrees of industry concentration. S. Rosen developed a theoretical model in which the threat effect of union organization causes employers of nonunion labor to take account of the union wage level in setting their wage offers. He then estimated values of λ of 38 percent in highly organized industries and of only 10 percent in lightly organized industries. The Stafford study found the highest union effect for the lowest occupational categories and the lowest effect for white-collar workers. G. Johnson and K. Youmans found that λ declines with education and is greater for the youngest and oldest age categories than for the middle-age categories. O. Ashenfelter estimated that unions increase the wages of black males by 21 percent as compared to 10 percent for white males. M. J. Boskin attempted to provide estimates of λ for all separate occupation-region-race-sex groups, but as R. Oaxaca has shown, its methodology was in error.

These studies, as well as others I have not mentioned, are all attempts to refine the basic model in order to arrive at *the* estimate (or set of estimates) of the relative wage impact of unionism. I am, however, a trifle skeptical about the appropriateness of this model because of its assumption that U_i is exogenous—although my skepticism is *not* widely shared by other labor economists. Consider the question of why wage differences net of quality and other factors might exist in the absence of unionism. Firms with production processes which are characterized by relatively high specific training requirements will attempt to maintain a low rate of labor turnover by paying higher wages than average; firms with lower training requirements, on the other hand, will maximize profits by paying lower than average wages (see J. Pencavel). Now workers in the high-wage firms will have a greater interest in the conditions of their employment than workers in low-wage firms, for the former are aware that they are unlikely to improve their lot by engaging in job search. One of the major functions of unionism is to regulate the nonwage conditions of employment for their members—including speed of production, grievance procedures, and seniority systems (see S. Slichter, ch. 2, and A. Alchian and H. Demsetz, p. 790). Thus, workers in what normally would be high-wage firms are more likely to demand unionism, and union organizers are more likely to supply their services to workers who are characterized by stable employment. This scenario suggests, holding labor quality and other factors constant, that for interindustry data such as Throop's (a) the wage level depends on unionism and the degree of specific training requirements, (b) the propensity to quit depends negatively on the wage level, and (c) unionism depends negatively on the propensity to quit. It is a straightforward matter to show that the ordinary least squares estimator of the effect of unionism on wages which does not both include the specific training requirements variable and take account of the joint determination of wages, the quit rate, and unionism will be biased in an upward direction. For micro data sets, the above argument suggests that union workers happen to be located in jobs which would have paid higher than predicted wages (on the basis of the included elements of X_i) even in the absence of unionism. In this case, the estimator of β will receive some of the credit which should go to the omitted specific training variable.

There are other approaches to the problem of the endogenicity of union membership (M. Reder, Ashenfelter and Johnson, and H. Levinson), but I will not go into detail at this time. The chief implication of this is that there is some cause to be skeptical concerning the accuracy of previous estimates of λ. What is needed to resolve this issue (and others not concerned with unionism) are data on individuals gathered jointly from households and establishments.

II. The Impact of Unionism on the Inequality of Income

A positive relative wage effect of unionism will have two effects on the personal distribution of income and welfare. First, the larger the union/nonunion relative wage the smaller will be employment in unionized relative to nonunion industries. Lewis (1963a) obtained an estimate of the elasticity of relative union/nonunion employment with respect to the relative wage of about minus one. This means that an increase in λ of five percentage points will, given an initial extent of organization of 25 percent, decrease union sector employment by (roughly) 3.8 percent and increase nonunion sector employment by 1.3 percent. H. G. Johnson and P. Mieszkowski used a two-sector general equilibrium model to investigate the effects of unionism on income distribution. After plugging in plausible values of the various parameters, they conclude that "most, if not all, of the gains of union labor are made at the expense of nonunionized workers, and not at the expense of earnings on capital." In addition, they calculate that the loss in aggregate welfare due to the inefficiency in the allocation of resources caused by unionism is only .33 percent (at λ equal to 15 percent).

Second, holding the size of the union and nonunion sectors constant, variations in λ will obviously influence the distribution of earnings. Whether the degree of income inequality is increased or decreased due to unionism depends on where union members would have placed in the distribution of earnings in the absence of unionism. Treating X_i in equation (1) as a composite variable (positively) influencing wages, the variance of the logarithm of individual wage rates is

$$(2)\quad \mathrm{var}\,(\log W_i) = \beta^2\,\mathrm{var}\,(U_i) + \gamma^2\,\mathrm{var}\,(X_i) + 2\beta\gamma\,\mathrm{cov}\,(U_i, X_i).$$

Unions increase (decrease) income inequality as $2\gamma b_{X\cdot U} \gtrless -\beta$, where $b_{X\cdot U}$ is the slope coefficient in a regression of X_i on U_i. In words, this means that in order for unionism to decrease income inequality it must be true that union members would, in the absence of unionism, be fairly well toward the lower end of the income distribution. This is, in fact, not the case. Union members generally possess characteristics which would put them in the middle of the income distribution, which means that $\mathrm{cov}(U_i, X_i)=0$, so that unionism probably has a *slight* disequalizing effect on the distribution of income (see A. Rees, pp. 98–99, and A. Blinder).

The interactive approach to the relative wage impact of unionism qualifies this conclusion somewhat. The proportion of black males who are union members is approximately the same as for whites, but the union relative wage effect is much greater for the former than the latter. Thus, the ratio of black to white wages was estimated by Ashenfelter to be 3.4 percent greater in 1967 than it would have been in the absence of unionism. On the other hand, the incidence of unionism among female workers is a third of its value for male workers, so unionism probably exacerbates the male-female wage differential. The incidence of unionism is greater in the lower than the higher occupational categories and so, by the Stafford estimates, is the relative wage effect, and this obviously tends to compress the wage structure. Thus, the conclusion that unions have little overall effect on income inequality is reinforced by the interactive approach.

III. Effect of Unionism on the Rate of Change of Money Wages

Like the other questions, this one has been around for a long time, and as in all but the last question, there remain many unresolved issues associated with it. Recent approaches to this problem have, of course, been in the context of the effect of unionism on the shape and position of the aggregate Phillips curve. First, reference to collective bargaining between unions and management was employed to justify variables, such as profit rates and the rate of price inflation, in some of the early wage equations (see G. L. Perry and O. Eckstein and T. Wilson). The significance of profits in the determination of union wages would appear to provide credence to bargaining models; it also seems to establish the functional distribution of income as an important factor in the inflationary process. However, more recent work has shown that, *whatever* the profit rate is doing on the right-hand side of wage equations, it has nothing to do with unionism. G. Pierson estimated separate wage equations for strongly unionized and weakly unionized industries and found that the profit rate was a more significant determinant of wages in the ***nonunion*** sector than in the union sector. Hamermesh (1970) constructed a wage series based on contract settlements and also found that profit rates did not have a significant effect on wage changes.

Second, there is a good deal of evidence that wages in the union sector are less sensitive to excess demand conditions than wages in the nonunion sector. The coefficient on the unemployment rate in the Hamermesh study was much smaller than in the earlier economywide equations. Ashenfelter, Johnson, and Pencavel estimated separate Phillips curves for unionized and nonunionized workers in manufacturing and found that the sum of the coefficients on the unemployment rate and its lagged value was $-.92$ in the nonunion sector and just $-.18$ in the union sector. Similar results were obtained by Hamermesh (1972). This finding is also consistent with the wage rigidity hypothesis advanced by Lewis (1963b) to explain variations in the union-nonunion wage differential over time.

Third, the importance of the question of the role of unions in the aggregate wage determination process rests on the degree to which nonunion wage changes are influenced by union wage changes and vice versa. E. Phelps has argued that since only one in four of all workers is a union member it is reasonable to ignore the influence of unionism. Similarly, R. Lucas and L. Rapping suggest that unions merely attempt to maintain a certain wage position relative to the nonunion sector and that it is therefore appropriate to analyze aggregate wage determination solely in terms of competitive factors. On the other hand, the presumption of models such as that of Eckstein and Wilson is that nonunion wages are largely influenced by union wages. Public policy over the past twelve years has reflected the latter view with the periodic imposition of voluntary or more-or-less mandatory controls on wage changes in the union sector. Which of these views is the more correct is an empirical question, but there has been little systematic work toward its resolution.

This completes my brief survey of recent trends in the economic analysis of trade unionism. My major conclusion is that while little progress has been made in modeling the behavior of trade unions—their objectives and the role of the bargaining process—there has been a great deal of sound empirical work on the economic effects of unionism. We know, for example, that unions have only a small effect on the distribution of income and that they tend to flatten the aggregate Phillips curve. We also know that the union-nonunion wage differential varies systematically across different parts of the labor force. There are many questions, some of which have fairly important policy implications, which have not been wrapped up, such as the effect of unionism on the position (as opposed to the shape) of the aggregate Phillips curve (or the "natural" unemployment rate). Perhaps in the next few years there will be an increase in the amount of resources devoted to a rigorous examination of these questions.

Economics of Time and Labor Supply

By H. G. Lewis*

The trail markers in recent research on labor supply are Clarence D. Long's book on the labor force; Jacob Mincer's paper on the labor force participation of married women; Gary S. Becker's paper on the allocation of time; William G. Bowen's and T. Aldrich Finegan's massive volume on labor force participation; the Becker-Gilbert R. Ghez monograph on the allocation of time and goods over the life cycle, which has been circulating in manuscript for several years but is not yet published; James Heckman's unpublished but forthcoming paper on shadow wages, market wages, and labor supply; the Glen G. Cain-Harold W. Watts volume which contains nine papers by a total of thirteen economists; and the Watts-Albert E. Rees *Final Report of the New Jersey Graduated Work Incentive Experiment.*

We now have literally hundreds of empirical labor force participation, weeks worked, hours worked per week and per year equations. What can they do for us in understanding time series variations in these various dimensions of labor supply? Differences in labor supply behavior among countries? Within countries by sex and other divisions of the population? The consequences of a national negative income tax scheme?

When belatedly I began the preparation of this paper, I became acutely aware that a convincing evaluation could not be accomplished single-handedly within a few weeks and in the scope of a short paper, even with the help of the recent Julie DaVanzo-Dennis N. DeTray-David H. Greenberg sensitivity analysis and Cain and Watts's effort at summary and synthesis. The sheer bulk of the pertinent literature and the seeming diversity of its findings are simply too great. Even now I have not read much of this literature, to say nothing of having studied, reflected upon, and reconciled it. I agreed reluctantly to prepare today's paper, but the assignment has aroused my curiosity so much that in the months ahead I am going to try to put the hours-of-work puzzle together. I am encouraged by an earlier, somewhat similar experience—that of evaluating research on the relative wage effects of unionism—to think that a substantial part of the puzzle can be assembled. What follows in this paper, therefore, is not a completed evaluation, but impressions, and these will be focused mainly on the negative income tax experiments.

One becomes most aware of the diversity of findings, of course, in a context such as that of predicting with some numerical precision the consequences of a negative income tax (*NIT*) scheme. For such a problem it can make a great deal of difference whether a relevant elasticity is 0.05 or 0.25. Yet it is important that we not lose sight of the forest because of the differences among the trees. We have come a long way toward understanding the division of labor within the family, not in family by family detail, but on the average, and this is no mean accomplishment. The findings here are so well known, I judge, that I won't try to summarize them. Furthermore, I have the impression that there is a considerable degree of agreement that long-run, uncompensated, own-wage elasticities of hours worked by married, prime-age males are negative and numerically closer to zero than to unity: a figure such as -0.15 is, I think, in the ballpark.

---

* Department of Economics, University of Chicago.

However, for the *NIT* problem we need to know more—the corresponding income elasticity, for example, and here my impression of the findings is one of marked diversity.

I turn now to the *NIT* experiments, especially the *Final Report* of the New Jersey-Pennsylvania experiment. First three general comments:

1. The *Final Report* almost defies anyone to study it. There is no detailed subject index, no list of tables, no detailed statistical appendix in which one can find answers to such questions as: What proportion of the white, continuous husband-wife, experimental families not on welfare received no *NIT* payments at all? One such payment? Two? And so on. Or what proportion of the male heads were multiple jobholders? I am pleased to hear that the *Final Report* is not the *last* report. I trust that the next *Final Report* will correct this defect of the first *Final Report.*

2. The four *NIT* experiments (New Jersey-Pennsylvania, Rural, Gary, and Seattle-Denver) are producing a unique set of panel data in which low-income families are presented with an alternative budget restraint involving much lower net wages and much higher nonwage income than their usual budget restraint. I hope that the data emerging from these experiments will be made generally available on tape or cards.

3. It should be surprising to some economists to learn that a final report on the first of the experiments already is available. The New Jersey-Pennsylvania experiment was designed, of course, to provide *NIT* payments to eligible families for only three years and the last such payment was made in September 1972. But presumably an *NIT* experiment has income effects and intertemporal substitution effects, not only during the experimental (or payment) period, but after it as well. I am disappointed that the experiment was not designed to continue the data assembly and analysis for a postexperimental period of two or three years, at least, and hope that some such effort will be made in one or more of the other experiments. Furthermore, the certain prospect this year of an *NIT* budget restraint option in the fairly near future will have income and substitution effects on this year's behavior of some families. Here, too, I am unhappy that some of the experimental families were not told at their enrollment in the experiment that, say, three years later they would become eligible for *NIT* payments for a period of three years, and that data were not gathered and analyzed for the preexperimental as well as the experimental period.

What did the New Jersey-Pennsylvania experiment discover? Although the counterintuitive findings for black families and, to a lesser extent, those for the Spanish-speaking families are a puzzle that deserves further study, I discuss here only the results for white families. First, some figures for the white, continuous husband-wife, experimental families just preceding their enrollment in the *NIT* experiment. Family size averaged close to six persons with an average of one to two children less than six years of age. Mean family hours of work per week was forty-two; mean family earnings $100 per week; mean family income $111 per week, with 23 percent of the families below the poverty income line, 34 percent at 100–124 percent of the line, and 43 percent at 125–150 percent of the line. The male heads averaged thirty-six years of age and ten years of schooling; 97 percent were labor force participants of whom 5 to 6 percent were unemployed; their mean hours of work per week was thirty-five and their mean wage about $2.50 per hour. Only one-sixth of the wives were labor force participants and the wives averaged about four hours of work per week and a wage of about $2.10.

The guarantees and implicit tax rates of the *NIT* schemes for these families varied from family to family; the mean guarantee was 90 percent of the poverty line and the mean tax rate was 51 percent. Most of these families resided in Scranton, Pennsylvania.

At first blush the low labor force participation rates for the wives and large family size may appear surprising. Recall, however, that only families with able-bodied male heads eighteen to fifty-eight years of age and with a 1968 family income not in excess of 150 percent of the poverty line were enrolled in the experiment and that the poverty line increased with family size.

Under a national *NIT* scheme of the kind examined in the experiment, many families will never choose the *NIT* option —that is, they will behave in such a way that they do not receive *NIT* payments at any time in their lifetime. We would like the experimental findings to tell us, first of all, the characteristics—in terms of family size, nonwage income, and wage profiles—of such families as they relate to the *NIT* parameters (guarantee, tax rate, poverty line). Second, for the families who would receive *NIT* payments, we would like to know their hours of work response to the *NIT*, both during the payment periods and at other times, stated as a function of the *NIT* parameters and the family's nonwage income, wage, and other relevant characteristics. That is, we would like the findings to come in the form of a *response function* that will tell us who will opt for the *NIT* and their responses.

The research staff of the experiment tried diligently to estimate such a function for responses during the three-year experimental period. For male heads of families with an average normal income (about 120 percent of the poverty line) under an *NIT* scheme with a guarantee of 100 percent of the poverty line and a 50 percent tax rate, they estimated that the effect of the *NIT* on mean hours of work per week was a reduction of about two and one-half hours during the middle eight quarters of the experiment and about seven and one-half hours during the last year. The disincentive effects, they estimated, were negligible for families with normal income near the break-even level of their *NIT* plan, but rose markedly as normal income declined below the break-even level. The estimated disincentive effects also rose substantially as the tax rate increased *or the guarantee fell*. The last result, of course, is surprising, demands explanation, and casts a cloud of uncertainty over the estimated response surface.

For the wives in these families, the labor force participation rate fell, because of the *NIT*, from about one-sixth to about one-twelfth and hours worked from about four per week to about two. The measured disincentives were greatest during the first two years, there was a general tendency for the disincentives to increase with the *NIT* guarantee, but variation in the *NIT* tax rate produced little variation in measured response. There is some evidence that the disincentive effects *increased* as normal income increased, a result that is not so surprising as at first it may seem.

Some of the derivatives of the estimated response functions with respect to guarantee, tax rate, and family income capacity are highly questionable and this is unfortunate. But put derivatives aside and simply evaluate the functions for intact white families with able-bodied male heads eighteen to fifty-eight years of age near the center of gravity of the experiment's observations (guarantee of 100 percent of the poverty line, tax rate of 50 percent, normal income about 120 percent of the poverty line). Are the estimated responses that I have cited what we can expect for such families under a national and permanent *NIT* with the same parameters during periods in which they are receiving payments? I see no reason for supposing that these estimates are grossly misleading for a national, permanent *NIT* during its initial years for such families that expect to receive the *NIT* payments only temporarily—that is, for a relatively small fraction of their remaining working years. I would expect the disincentives to become somewhat larger after the *NIT* had become more familiar and better understood and especially to be larger for families expecting to receive *NIT* payments more or less permanently.

For illustrative purposes, consider the following lifetime utility function and budget restraint for a husband(m)-wife(f) family:

Utility function:

$$u = \left(\sum_{t=1}^{n} u_t^{(\sigma-1)/\sigma} \right)^{\sigma/(\sigma-1)},$$

where σ is either zero or 0.2;

$$u_t = \text{Min}\,(u_{mt}, u_{ft}); \qquad 5u_{mt} = (\lambda_{mt}^{-1} + x_{mt}^{-1})^{-1};$$
$$u_{ft} = (9\lambda_{ft}^{-1} + x_{ft}^{-1})^{-1}$$

Budget restraint:

$$A + \sum_{t=1}^{n} 100(w_{mt} + w_{ft}) = \sum_{t=1}^{n} \pi_t u_t;$$

where u denotes utility, t the week in a remaining n-week lifetime, 100 is the assumed number of hours per week disposable for either leisure time λ or market work, x is market goods consumption, the w's are real market wage rates per hour in terms of market goods, A is initial net real assets, π_t is the shadow price of u_t, and I assume for simplicity a zero interest rate. The illustration is a simplification, to put it mildly, of the Becker-Ghez model and the substitution elasticities in the illustration are not those estimated by them, though they are not, I think, preposterously different.

Assume that A is zero and that w_m and w_f do not vary over the lifetime, with $w_m = \$2.56$ per hour and $w_f = \$1.64$ per hour. At these values the husband works 40.4 hours per week, the wife 16.8 hours, and together they earn $130.91 per week. I take these as the *base* values for measuring the impact of the *NIT*.

Now offer the family a permanent *NIT* option with a 50 percent tax rate and a weekly guarantee of $67.50 (a weekly break-even of $135.00). Turn to Table 1, row 1. The first six columns show the ratio of hours worked under this *NIT* experiment to base hours. The husband's hours fall by 30 percent and the wife's by 62 percent.

Suppose that the preceding *NIT* option is offered now for a period amounting to one-fifth the expected remaining lifetime of the family. Then the lifetime income effects of the *NIT* are smaller than on line (1), but there may be intertemporal substitution effects as well. There are no intertemporal substitution effects on line (1). Line (2) assumes that the intertemporal substitution elasticity σ is zero, so that line (2) differs from line (1) during the experimental period only in having smaller income effects. Hence during the experimental period, hours worked fall by less on line (2) than on line (1). Notice that hours worked fall slightly after the experimental period because of the increase in lifetime income produced by the *NIT*. Line (3) assumes an intertemporal substitution elasticity equal to 0.2. The intertemporal substitution possibilities present on line (3) have two consequences. First, the *income* effects are larger than on line (2) and these will tend to reduce hours both during and after the experiment. Second, and more important, intertemporal substitution between the experimental and later periods by itself causes hours worked to fall during

TABLE 1—ILLUSTRATION OF DISINCENTIVE EFFECTS OF *NIT* EXPERIMENTS IN A LIFETIME CONTEXT

Experimental Period and Value of σ	Ratio of Husband's Hours to Base Hours (Base=40.4)			Ratio of Wife's Hours to Base Hours (Base=16.8)		
	During Experiment (1)	After Experiment (2)	Lifetime Mean (3)	During Experiment (4)	After Experiment (5)	Lifetime Mean (6)
(1) Lifetime; σ irrelevant	0.70	—	0.70	0.38	—	0.38
(2) $\frac{1}{8}$ of lifetime; $\sigma=0$	0.76	0.99	0.95	0.55	0.98	0.89
(3) $\frac{1}{8}$ of lifetime; $\sigma=0.2$	0.62	1.01	0.93	0.12	1.04	0.85
(4) $\frac{1}{8}$ of lifetime; $\sigma=0^{a}$	0.99^{b}	0.996	0.995	0.56	0.99	0.90
(5) $\frac{1}{8}$ of lifetime; $\sigma=0.2^{a}$	0.99^{b}	1.004	1.00	0.44	1.01	0.90

[a] See text for explanation.

[b] By assumption; see text.

the experimental period and to *rise* thereafter. Thus, in the illustration, hours worked fall by more on line (3) than on lines (1) and (2) during the experimental period, but rise slightly after the experiment. From the comparison of lines (2) and (3) with line (1), it appears to be unclear whether a short-duration *NIT* experiment will lead to under- rather than overestimation of the disincentive effects of a permanent *NIT* scheme.

However, lines (1), (2), and (3) assume that workers freely can choose their hours of work at wage rates given by the market —that is, that employers are indifferent with respect to the hours of work of their employees. Thus, for example, on line (3) the husband, in response to the *NIT*, cuts his hours per week from 40.4 to 25.0 during the experiment and then raises his hours to 40.9 thereafter, presumably without having to change employers. It seems more reasonable to suppose that changes in hours of work of this magnitude sometimes, perhaps often, would involve changing jobs with associated search costs and, for some, loss of seniority (specific human capital) benefits. (In this connection it would be useful to know what fraction of the male heads in the experiment were multiple jobholders, their hours worked on the secondary job, and the impact of the *NIT* experiment on these hours.) It also seems likely that such costs typically will be greater for male heads with a more or less permanent, full-time attachment to the labor force than for the wives, who usually have less firm labor force attachments.

Lines (4) and (5) of the illustration assume that these job-change costs are sufficiently great for the husband in the context of the short-duration experiment that he avoids changing jobs, though he does cut his hours slightly during the experiment. (This assumption is consistent with the finding in the experiment that the experimental *NIT* did not lead to an increase in job turnover for male heads, though it does not explain reduced job turnover.) In other respects the model for lines (4) and (5) is the same as that for the preceding lines. In particular, it is still assumed that the wife freely chooses her hours.

The effect of the restraint on the husband's hours assumed in the illustration is to reduce both the lifetime income effects of the experiment, as can be seen by comparing line (2) with line (4) for the wife's hours, and especially the intertemporal substitution effects, as shown by a similar comparison of line (3) with line (5).

In the illustration the wife cuts her hours during the experiment by less on lines (4) and (5) than on line (1). I don't mean to argue that this proves that the short duration of the experiment led to underestimation for married women of the disincentive effects of a similar but permanent *NIT* program, but only that the *Final Report* conceivably may not be correct in arguing the opposite. Of course, I have set the model up in such a way as to get the results on lines (4) and (5), but that does not make the results wrong.

As for the husbands, there is another reason for suspecting that the long-run disincentive effects may have been underestimated, namely, that substitution possibilities within the household between time and market goods may be substantially larger in the long run than in the short run. Do-it-yourself that is neither thumb twiddling to the doer nor malingering to the observer requires planning and preparation.

DISCUSSION

PAULA E. STEPHAN, Georgia State University: Gregg Lewis focuses upon possible effects of the negative income tax (*NIT*) within the traditional framework of the work-leisure choice. Lewis applies the familiar tools of comparative statics, albeit to multiple time periods. Lewis' results are of interest since they remind us that the *NIT* market-work disincentive results are dependent upon the length of time of the *NIT* and the intertemporal elasticity of substitution. With regard to the first of these points, we should be cautioned that the *NIT* work effects are dependent upon the length of time of the *NIT* relative to the horizon of the individual, not relative to his working life. Indeed, one likely reason the poor are poor is because of an abbreviated horizon.

The *NIT* is a useful vehicle for analyzing aspects of time allocation. I find it somewhat disappointing, however, that Lewis chooses to analyze the question within the parochial framework of utility maximization. It is useful to point out that other approaches exist. In particular, Lewis does not mention that the *NIT* can affect human capital accumulation. Consider the human capital approach which states that the objective of the individual is to maximize the present value of income net of investment costs. Within this framework, it can be shown that by lowering the after-tax value of the individual's time the *NIT* will lower the indirect cost of human capital investment as well as the present value of the benefit stream arising from the human capital investment. Because the *NIT* does not alter the cost of direct inputs used in human capital production, however, the *NIT* will cause the present value of benefits arising from the human capital investment to decrease relative to the cost of investment. As a result, the *NIT* leads to a flatter human capital profile. One consequence of this may be to keep persons permanently on the negative income tax roles. Since earnings are lower in the early and late years of the life cycle, the *NIT* may expect to enroll primarily the young and the old. If, however, the *NIT* has human capital disincentive effects, today's young enrollees may prove to be eligible in the mid-years as well as in the late years of their lives.

Just as the Lewis work disincentive effects depend upon the length of time of the *NIT* relative to the horizon of the individual, so too do the human capital disincentive effects. While the present value of benefits arising from human capital production depends upon the relative length of time of the *NIT*, the costs do not. As a result, a nonpermanent *NIT* will have smaller human capital disincentive effects than a permanent *NIT*. Indeed, when the *NIT* is not permanent, it is possible to conceive of a situation where the *NIT* operates to augment the quantity of human capital produced by the individual. If, for example, the *NIT* is relatively short-lived, the cost of human capital production may well decrease more than the resulting benefits and we may find persons accumulating human capital inventories.

The Lewis view sees the wage rate as exogenous and hours of work as endogenous and demonstrates that the *NIT* can lower the number of hours worked. The human capital view sees the combined number of hours of work and training as exogenous and the wage rate as endogenous and demonstrates that a permanent *NIT* can flatten the wage profile. Both are, of course, partial views of the world. Yet these partial views are seldom joined. As a profession we teach our students that the hours-of-leisure variable is solved in a utility maximization framework while the wage-rate variable is solved by the technique of lifetime income maximization.

Recent work by G. S. Becker and G. R. Ghez attempts to unite these two approaches by depicting the life cycle as a series of static utility-maximizing decisions superimposed upon an endogenous wage rate which changes over time as the human capital stock is altered by the individual's investment decision. Following the Becker-Ghez approach, one could argue that the *NIT* acts to augment leisure not only because of utility considerations, but also because human capital considerations lead to a dampening of the value of time.

The problem with the Becker-Ghez approach is that partial solutions derived statically do not necessarily provide the solution to a dynamic problem. Because time can be allocated between labor, leisure, and training, human capital decisions are affected by utility considerations as well as profitability considerations. Further, human capital decisions as well as utility considerations affect hours of leisure. Consequently time allocation over the life cycle should be treated in the context of a dynamic model which recognizes that today's decisions influence the decisions to be made tomorrow. Such a model was presented by Frank Stafford and me at the 1972 meetings in Toronto. Further developments along these lines have been set forth in a paper by A. S. Blinder and L. W. Weiss. The results of these models are of interest because one can deduce properties of the time paths of labor, leisure, and training over the life cycle. Unfortunately, as is the case with most dynamic models, it is not possible to obtain explicit solutions to these models. Yet it does seem that insights into possible effects of the *NIT* on life-cycle labor supply and human capital accumulation could be achieved through simulating some of the functional forms of the dynamic models developed to date.

Apart from the fact that dynamic models may be successful in explaining life-cycle labor supply and earnings, the conclusion we are forced to draw is one which is far too familiar to economists: namely, a tradeoff exists among the progression of models we have described. As we endogenate the variables, insights provided in the form of explicit solutions vanish. On the other hand, this process is useful since it will at least alert us to the interdependencies that exist and to how these interdependencies may alter the conclusions of simpler models. As a result, this process will allow us to test the conclusions of our simpler models. Properties of these models which prove to be unaltered by the more complete models can then be considered robust.

PAST DEVELOPMENTS AND FUTURE PROSPECTS FOR ETHNIC MINORITY GROUPS

Three Phases of Cliometric Research On Slavery and its Aftermath

By ROBERT WILLIAM FOGEL*

The cliometric investigation of slavery and its aftermath is now nearly two decades old. Initiated by the path-breaking paper presented by Alfred H. Conrad and John R. Meyer in 1957, it has been carried forward in more than 100 subsequent papers, doctoral dissertations, and books.[1] This extensive scholarly effort has contributed not only to the reshaping of the discipline of economic history but has greatly altered our understanding of the nature of slave society and, most important, has helped to reveal the remarkable record of black achievement in the protracted and difficult struggle to overcome racist oppression. It is not possible in this brief paper to review adequately the many contributions to the reinterpretation of the slave economy. I would, however, like to outline what I believe to be the three main phases of cliometric research on the subject and to suggest some priorities for future research.

During the first phase, which extended roughly from 1957 to 1969, cliometric research was focused on three issues: the profitability of an investment in slaves to slaveholders; the economic viability of the slave economy; and the effect of slavery on southern economic growth. All three of these issues were, of course, raised in the original Conrad and Meyer paper, but not all of them were explored to the same extent by either Conrad and Meyer or by their successors. Much of the initial work focused on the issues of profitability and viability, partly, perhaps, because these seemed to be more tractable than the question of growth, partly because the evidence bearing on profitability appeared to be more readily available.

The debates on profitability have involved both theoretical and empirical issues. Much of the discussion has turned on the equation originally employed by Conrad and Meyer to estimate the rate of return on male slaves. They became involved in the difficult task of estimating the average amount of land and capital employed per slave, although this issue could have been finessed by employing a slightly different variant of their basic equation.[2] More vexing were the implicit assumptions that all twenty-year-old slaves lived for exactly thirty additional years (the approximate life expectation of male slaves at age twenty) and that between ages twenty and fifty average annual earnings of adult males were invariant. Robert Evans, Jr. and N. G. Butlin improved on the demographic assumption by providing estimates of the age-specific death rates of slaves that were quite similar, even though Butlin's estimates were derived from the Jamaican life-table and Evans' were derived from the published data in the *U.S.* census of 1850. It was not, however, possible to obtain estimates of the age-earnings profile (the average earnings of a cohort of slaves at each age from birth to the death of the last member of the cohort) from published sources.

[2] See E. Saraydar, R. Sutch, and J. D. Foust and D. E. Swan. Also, see Fogel and Engerman 1974a, vol. 2, p. 66.

The principal contribution on the issue of viability prior to 1969 was made by Y. Yasuba, who pointed out that the rate of return on the purchase price of a slave by itself was insufficient to establish that slavery was economically viable. Yasuba proposed to measure viability by the capitalized rent on slaves, that is, by the difference between the market price of a slave at a given age and the cost of rearing him to that age. Yasuba's approach was further refined by T. Bergstrom who proposed to use the capitalized rent at age zero (the zero-age price of a slave), which has been called the price of a "birthright."[3]

The principal contribution on the question of southern economic growth was made by R. A. Easterlin who, after working out regional income accounts, discovered that between 1840 and 1860 the per capita income of the South grew by 1.3 percent per annum. Engerman, by taking account of Texas, raised this figure to 1.7 percent, thus revealing that during two decades preceding the Civil War the slave South was growing more rapidly than the free North. While these findings clearly refuted the belief that the antebellum South was stagnating, they did not settle the counterfactual questions of whether slavery retarded economic growth during the antebellum era or whether the legacy of slavery retarded growth during the postbellum era.[4]

The principal feature of the second phase is the massive effort to uncover primary data bearing on the operation of the slave economy. This phase of the cliometric investigation of slavery was launched in the early 1960's when Parker and Robert E. Gallman began the collection of a random sample from the manuscript schedules of the *U.S.* census for 1860. By 1968 they had not only retrieved, but put in machine-readable form, information on 5,000 southern farms and 40,000 slaves. Shortly thereafter they, various of their students, and others began to illuminate the ongoing debates on slavery by providing far better evidence than had hitherto been available. Even more important, this new data base stimulated a substantial enlargement of the set of issues under consideration. Wright (1969) examined the distribution of wealth among free whites in the South and probed into the question of economies of scale in cotton production; Foust analyzed the role played by the yeoman farmer in the westward expansion of cotton production; Gallman, as well as R. C. Battalio and J. Kagel, estimated the degree to which large slave plantations were self-sufficient in the production of food.

The search for primary data was given new impetus by the attempt to use the geometric index of total factor productivity to compare the relative efficiency of northern and southern agriculture for the year 1860. The year 1860 was singled out because the availability of the Parker-Gallman sample permitted a comparison of the efficiency of large and small farms within the South. When, however, the first crude measurements produced the unexpected result that southern slave agriculture was substantially more efficient than northern free agriculture, it became clear that the evidence contained in the Parker-Gallman sample, by itself, was inadequate for dealing with this complex issue.

---

[3] Engerman and I independently hit upon the same approach in 1969.

[4] Papers probing these questions include W. N. Parker, C. Pope, P. Passell and G. Wright, Wright 1974b, and L. J. Kotlikoff and S. Pinera.

In our 1971 essay, Engerman and I argued that what showed up as the superior efficiency of slave agriculture in these indexes was probably due, in large part, to the mismeasurement of various of the inputs, particularly the labor input. For these indexes had been constructed on the assumption that hours worked per man-year were the same on southern slave plantations as on the free farms of the North. This, we conjectured, was probably wrong; it was likely that slaves worked more hours per day and more days per year than free farmers. We therefore launched a search for the additional data needed to measure the length of the slave and free work-years, to take adequate account of the much higher proportion of women and children in the slave than in the free labor force, and to determine the skill composition of the respective labor forces.

This search—a collective effort that was carried forward by a team of over thirty researchers, assisted and advised by more than a dozen leading scholars of antebellum history—brought forth an enormous increase in the available body of evidence bearing on slavery. One component of the new data base, a sample of 5,700 estates containing information on 77,000 slaves who lived between 1770 and 1865, was retrieved from the probate records of southern courts. This body of information made it possible to construct age-price profiles for slaves, from which the long-missing age-earnings profile could be computed. The age-earnings profile was not only needed for the resolution of the issue of profitability, but was critical for the issue of efficiency as well, since it provided the basis for converting the unadjusted measures of the labor input of women, children, the aged, and the disabled into full-hand equivalents. About 10 percent of the estates in the probate sample also provided information on the skill composition of the slave labor force.

A second component of the new data base is a sample of the business records of roughly 100 large plantations containing either highly detailed information on the organization of production (including records of the daily activities of each slave in the labor force) or demographic information needed to adjust the labor input of women. For many of these plantations the demographic record extends over a period of at least 75 years, thus bearing on the lives of three or more generations of slaves. This source, which contains information on roughly 20,000 slaves, also yielded much important evidence on the skill composition of the slave labor force. Still other important bodies of systematic data bearing on the issue of efficiency were found in slave-trading and mortality records. The various new samples, together with the Parker-Gallman sample, contain information on over 250,000 slaves, or about 4 percent of the slaves who ever lived in the United States or the colonies out of which it was formed.[5]

Surprisingly, the evidence culled from the new sources did not sustain our original conjecture that the relative efficiency of slave agriculture was due largely to the failure to measure the labor input in man-hours. Quite the contrary, the evidence indicated that the work-year of free northern farmers averaged over 3,100 hours while that of slaves on large plantations averaged about 2,800 hours (Olson and Fogel).

---

[5] More detailed descriptions of the types of information contained in the probate and large-plantation samples are contained in J. Metzer, R. H. Steckel, and J. F. Olson and Fogel. The other samples are described in Fogel and Engerman 1974a and 1974b.

If the finding that slave work-year was actually 10 percent shorter than that of free farmers in the North seems too ridiculous to be taken seriously, it is because most of the traditional portrayals of slavery have been based on the naive assumption, to which we originally subscribed, that the greater exploitation of slaves must have taken the form of the lengthening of the work-year.

But as every trade unionist who has grappled with the problem of speedup knows, it is possible to increase the real length of the work-year, even while reducing the number of clock-time hours, by increasing the intensity of work per hour. This point, which was emphasized in *Time On The Cross*, has been further illuminated by the recent work of Metzer and Olson. Their preliminary findings, summarized in the paper by Olson and Fogel, indicate that slaves worked 82 percent more intensely per hour than did the free farmers of the North. Thus the typical slave on a large plantation produced as much in thirty-three minutes as did the typical free farmer in an hour. It follows that if one measures the length of the work-year not in clock-time hours but in hours of equal labor intensity (equal-efficiency hours), the slave work-year was actually 65 percent longer than the free work-year.

Once it is recognized that the fundamental form of the exploitation of slave labor was through increasing intensity per hour rather than through an increase in clock-time hours per year, many paradoxes resolve themselves. The longer rest breaks during the work day and the greater time off on Sundays for slaves than for free men appear not as boons that slaveowners granted to their chattel, but as conditions for achieving the desired level of intensity. The finding that slaves earned slightly more income per clock-time hour loses its startling quality when it is realized that their pay per equal-efficiency hour was 37 percent less than that of free men.

No aspect of *Time On The Cross* has occasioned more debate than the finding that slaves were more efficient and harder working than their free counterparts. Some scholars have suggested that the total-factor-productivity index used to compare the relative efficiency of free countries cannot be applied to a comparison of the free North and the slave South—that in this instance a morally weighted index of efficiency is required.[6] However, the issue of the relative efficiency of slave labor did not originate with *Time On The Cross*. It is an issue with a long history that traces back to such commentators on slavery as Adam Smith, Alexis de Tocqueville, Cassius Marcellus Clay, Hinton Rowan Helper, Frederick Law Olmsted, and John E. Cairnes. Is the geometric index of total factor productivity appropriate to the resolution of the question of the efficiency of slave labor as that question actually evolved in historical literature?

Much of chapters five and six of *Time On The Cross* is devoted to reviewing both the pre- and post-Civil War debates on the inefficiency of slave agriculture and slave labor. From this review it is clear that what the critics of slavery meant was: other inputs held constant, but substituting slave for free labor, and slave managers for free managers, the output of slave farms would be much less than the output of free farms. About this "fact" Clay, Helper, Olmsted and most other antislavery critics had no doubt. This confidence stemmed from the conviction that slavery "degraded" labor, that slavery turned plantation owners into "idlers," that, "comparing man with man," slave laborers were less than half as productive as whites, that Africans were "far less adapted for steady, uninterrupted labor than we are," and that "white labourers of equal intelligence and under equal stimulus will cut twice as much wood, split twice as many rails, and hoe a third more corn in a day than Negroes." (See Clay, p. 204, and Olmsted, pp. 91, 467–68.)

---

[6] See P. David and P. Temin 1974, especially pp. 778–83.

Nor does the geometric index of total factor productivity do violence to the issue of efficiency as it was perceived and discussed by the principal scholars who preceded us. Certainly neither U. B. Phillips, nor L. C. Gray, nor R. B. Flanders, nor R. R. Russel, nor K. M. Stampp were talking about a morally weighted measure of productivity, but of the comparative efficiency of slave and free labor, in just the manner that this issue was raised by the antebellum critics of slavery. In Gray's words:

> The discussion of efficiency of Negro slave labor has been befogged by a failure to distinguish between those industrial qualities peculiar to Negro labor and those attributable to the influence of slavery. There has been a tendency to assume that all the laziness and incapacity exhibited by the Negro are ascribable to his status as a slave. This confusion has been largely the outgrowth of the arbitrary assumption that slave labor must be inherently less economic than free labor because slave labor is given grudgingly and half-heartedly, while free labor is spurred by self-interest. Turgot and Adam Smith developed this attitude, and it soon became a commonplace of economic generalization, accepted even by some Southern writers. Francis A. Walker gave the formula an eloquent presentation: "The whip," he wrote, "only stimulates the flesh on which it is laid. It does not reach the parts of the man where lie the springs of action. No brutality of rule can evoke even the whole physical power of a human being." Cairnes recognized three fundamental elements of inefficiency in slave labor: "It is given reluctantly; it is unskillful; it is wanting in versatility.". . .
>
> Many contemporary writers, including some of proslavery sympathies, assumed that slave labor was intrinsically uneconomical as compared with free labor in general farming. Yet, in the physical operations of general farming slaves frequently displayed considerable skill. A contemporary writer asserted, "In the use of the axe, hoe, scythe and cradle, or driving and training teams, the practiced Negro of Georgia is surpassed by few white men I ever saw." It was admitted by some observers that slaves could cultivate as large an acreage of corn or wheat per hand as could a free laborer. Even in the care of livestock it was possible to find reliable individual Negroes to whom these functions could be entrusted. The inferiority of Negro slave labor in general farming was not due to the incapacity of the Negro to perform the manual operations involved, most of which, in that period when farm machinery was but little employed, were not more complex than in producing the staples. Indeed, general farming with slave labor at times proved successful. Where it was unprofitable, this was due mainly to three conditions: (1) A larger amount of supervision per unit of labor was required than in less diversified forms of agriculture, which is also true when free Negro or white labor is employed; (2) In a number of regions general farming was severely handicapped for lack of a home market; (3) The competitive superiority of cotton and sugar enabled planters employing virgin soils to offer higher prices for slaves than could be afforded in general farming. [pp. 462–63, 469]

The index of total factor productivity is, then, an appropriate instrument for resolving the issue of efficiency as it has been raised and debated in the historical literature for more than a century. And the results of the measurements performed with this index directly refute the calumny that blacks were less efficient or less hardworking than their white counterparts. Not only has this old view been refuted, but the weight of evidence now indicates that blacks on large plantations produced nearly twice as much output per unit of time as whites. Surely this is the wrong time to assert that output per manhour, standardized for other inputs, is a morally biased and unacceptable measure of the efficiency of labor.

Of course, the fact that blacks were more efficient under slavery than were free laborers does not imply that black workers are inherently superior to white workers. There is every reason to believe that if whites had been forced to labor under the gang system and blacks had been free farmers, then white slaves would have been more efficient than free blacks. It was the system that forced men to work at the pace of an assembly line (called the gang) that made labor more efficient, not race. Nor does greater efficiency mean greater good. Indeed the whole point of Table 3 of *Time On The Cross* was to demonstrate that freedom has value and that the loss of freedom was greater than the gain in measured output (vol. 1, pp. 244–46).

The principal feature of the third phase of cliometric research on slavery is the shift of emphasis from how the slave system worked to the recovery of black history. The onset of the third phase has not brought the second to an end. Rather, the two phases coexist, each giving vitality to the other. The effort to direct cliometric research toward the recovery of black history is, in fact, a direct consequence of the massive hunt for evidence bearing on the relative efficiency of slave agriculture. In the course of the search for the data needed to refine the measures of labor input, scholars have uncovered evidence that reveals new aspects of the widespread and successful struggle of blacks to overcome the worst features of the slave system.

The theme of black struggle under slavery is, of course, hardly new. But until recently many scholars have tended to treat this issue as if the main efforts of slaves to promote their self-interests were either revolutionary forms of violence, quasi-revolutionary flight for freedom, or covert but politically self-conscious forms of opposition that have been called "day to day resistance."[7] Deliberate warriors against oppression have, however, except perhaps for historically fleeting moments, always been an extremely small fraction of the population from which they sprang. What of the mass of slaves? Were they, as was so long argued, largely broken and corrupted by the system? Was there no room within the system, short of overt or covert political warfare, for those who had to bear the yoke of oppression to struggle for their self-interest? And if there was, what forms did these struggles take and with what success did they meet?

We have not yet acquired the hard evidence needed to answer these questions adequately, although there is considerable ground for believing that the desired evidence is recoverable. But what is already in hand clearly undermines the view that blacks were typically so crushed by the system of slavery that they were unable to advance their self-interests, to thwart the forces that militated against family solidarity, to acquire skills, and to become effective workers.[8] The findings on total factor productivity, for example, have exposed the frail basis for the contention that slaves were typically uneducable and incompetent laborers who "got into very bad habits of doing as little as possible" (Conrad et al., p. 539). Interestingly, some scholars have responded to the evidence indicating that blacks were actually harder working and more efficient than their white counterparts either by suggesting reverse racism or by arguing that for blacks to have been diligent implies that they must have accepted the morality and objectives of the master class (David and Temin

1975). This view of life under slavery surely oversimplifies the complex and contradictory forces that influenced the behavior of both slaves and masters and underestimates the extent to which the acquisition of skills and the improvement in the material conditions of life were wrung from the system.

Whatever the motives of the master class, slaves had good reasons of their own to be diligent and to acquire skills. Available evidence indicates that the level of the material conditions that slaves could obtain for themselves and for their children, the capacity to resist encroachments on the integrity of their families, and the opportunity to enlarge the scope for freedom of choice were all related to their effectiveness as workers (cf. Crawford 1975). On the matter of the diet, for example, statistical analysis of the Fisk University and WPA narratives of ex-slaves reveals that slaves who relied purely on the rations provided by masters had less varied diets than those who cultivated their own plots or engaged in hunting and fishing.[9] Analysis of the notarial records in New Orleans reveals that slave artisans and craftsmen were less likely to have been sold than ordinary field hands (Olson).

It is also a gross oversimplification to suggest that skills acquired by slaves were merely those that their masters conferred on them. While it may be true that economic forces generated by the market tended to make it profitable for masters to promote skill formation among their slaves (cf. C. D. Goldin), it also appears that powerful political forces operated in the opposite direction. It is now more than half a century since C. G. Woodson chronicled the efforts of blacks to acquire education during the antebellum era, finding that the effort reached its maximum extent and success prior to 1825. It is hard to come by the data needed to test Woodson's conjecture that between this date and 1860 black literacy rates declined by half under the impact of the reactionary political assault that made it a crime to teach slaves to read and write. On the other hand, there is strong evidence that between 1850 and 1860 this assault reduced by nearly half the number of large plantations on which blacks were the chief nonownership managers.[10] Increased pressure to enforce laws requiring the presence of white overseers appears to have been the principal reason for this decline.

The finding that in certain respects the attack on the material conditions of black life may have been more acute during the postbellum than during the antebellum era has led to a substantial increase in cliometric research into southern and black history covering the whole period from 1865 to the present. J. D. Reid, Jr., S. DeCanio, R. Ransom and Sutch, R. Shlomowitz, Wright, and R. Higgs are examining the institutional arrangements upon which the new economic order was constructed, seeking the mechanisms that undermined black economic life. Richard B. Freeman is examining the growth of discrimination against blacks in the labor market from 1870 through the depression of the 1930's, as well as assessing the factors which explain the reversal of this trend, especially after 1964. M. Hopkins and N. S. Cardell are measuring the change in the real income of blacks between 1850 and 1880. Engerman, E. Meeker, J. E. Eblen, and R. Farley are studying trends in black nuptiality, fertility, and mortality and their relationship to changing economic and social conditions.

One of the lessons of the latest phase of cliometric research is that the investigation of black economic history is an exercise in political economy in the fullest sense of the term. This is even more true for the postbellum era than for the antebellum era. The work of Reid, DeCanio, and Freeman strongly suggests that much of the deterioration in the material conditions of black life that took place after 1870 was due less to the operation of the unfettered forces of the market than to the use of state power to transfer income and wealth from blacks to whites. The evidence marshaled by Freeman indicates that licensure laws were used to squeeze blacks out of skilled crafts in which they had been strongly represented, while educational restrictions were used to prevent them from entering new crafts. He has also found that during the depression of the 1930's the number of blacks employed by state and local governments in the South fell by close to half even though the total number of government jobs in most southern states increased by the same fraction. These states, Freeman concludes, "appear to have replaced blacks with whites in menial jobs that had been undesirable in good times but became valuable in bad times" (ch. 8, p. 19).

---

[9] Fogel and Engerman 1974c. The problems involved in the quantification of the data in the ex-slave narratives and pitfalls of inferences made from these data are discussed in Crawford 1974.

[10] See Genovese and Rosett, especially the debate on the morning of October 24 and the response to the discussion on October 26.

* * *

In closing this essay it is worth recalling that during the 1960's there were raging debates as to whether black studies and black history had a legitimate place in the university curriculum. Many feared, not entirely without reason, that they would be artificial creations or, at best, "soft" subjects that undermined scholarly standards. How ironic it is, then, that black history has become the leading arena in the effort to apply rigorous quantitative methods to historical research.

Public Policy and Black Economic Progress: A Review of the Evidence

By BERNARD E. ANDERSON AND PHYLLIS A. WALLACE*

The 1960 decade was characterized by a marked improvement in the economic progress of the black community, narrowly defined as gains in black income and employment. The decade also brought new initiatives in public policy designed to influence economic growth and stability, human resource development, and equal employment opportunity. Although few of the economic and social programs developed during the 1960's were focused primarily on blacks, it is likely that the wide array of public policies pursued during the decade influenced both the pace and direction of changes in black employment and income.

The purpose of this paper is to summarize and evaluate the evidence compiled by economists to explain the pattern and determinants of change in the employment and income of blacks during the past decade. In the past few years, economists have given much attention to issues related to racial inequality, with much of the research conducted by a new generation of young economists who grew to maturity in the environment of the civil rights revolution when new perceptions and values on race relations were formed. Powerful analytic tools of analysis, conceptual paradigms, and data sources have been explored in an effort to better understand and explain the persistence of racial inequality. Yet there remains a considerable diversity of opinion on the meaning and significance of black progress in employment and income, and the extent to which the observed progress can be attributed to different types of public policy. It may be useful to summarize very briefly the broad trends in black income and employment between 1960 and 1974, and then evaluate the views of economists regarding the role of public policy in reducing racial inequality.

I. Trends in Black Employment and Income

During the 1960's, blacks experienced significant gains in the labor market, but the progress was uneven and discontinuous. Between 1961 and 1969, the number of blacks in the civilian labor force grew by 1,151,000, with adult black women accounting for 57 percent of that number. Black employment grew by slightly more than 1.5 million, distributed between 601,000 adult black men, and 755,000 adult black women. Black unemployment fell by 400,000, concentrated among black men, and the black unemployment rate declined sharply from 12.4 to 6.4 percent. Most of these gains were registered during the years 1965 through 1969, but the pause in economic activity between 1969 and 1971 reversed the trend in an unfavorable direction. During that two-year period blacks bore a disproportionately large share of the increase in unemployment, but failed to recoup their loss during the mild economic expansion of 1972 and 1973.

The 1960 decade also witnessed a marked degree of occupational upgrading within the black labor force. The proportion of all blacks in white-collar jobs rose from 16.1

---

* The Wharton School, University of Pennsylvania, and Sloan School of Management, Massachusetts Institute of Technology, respectively.

percent to 27.9 percent, with marked growth in the number of blacks in professional, technical, and clerical occupations. The proportion of blacks employed as skilled craftsmen also increased markedly, while those in unskilled labor and domestic service declined sharply. Blacks registered respectable gains in some industries such as banking, insurance, and utilities where black workers in the past had not been greeted with open arms. Most of the occupational gains were concentrated among younger blacks who entered the labor market with relatively greater schooling and job skills in comparison with older blacks in the labor market.

Yet despite the favorable occupational gains, blacks were still less likely than whites to get into the higher paying jobs, and were still concentrated in low-wage industries. Moreover, blacks continue to comprise a disproportionately large share of the net addition of labor in occupations and industries with limited opportunities for upgrading and with high sensitivity to cyclical fluctuations in the economy.

The ambivalence of black economic progress may be observed in earnings trends. The median income of black families doubled between 1960 and 1970, while the black/white income ratio increased from .55 to .64. The earnings improvement was evident across a wide spectrum, with the percent of black males earning less than $3,000 declining markedly from 40 percent in 1959 to 22 percent in 1969. Among black females, the proportion earning less than $3,000 per year declined from 75 to 52 percent. Conversely, the percent of black men earning more than $10,000 rose from 3 to 9 percent, while the proportion of black women in that earnings category increased from less than 1 percent to 5 percent.

Still, the dollar gap between whites and blacks continued to rise throughout the decade, reaching close to $4,700 in 1972. Also, while the number of blacks in poverty declined by 2.2 million between 1959 and 1970, the flight from poverty among blacks occurred at less than half the rate experienced by low-income whites. Further evidence of disparity is found in the black/white differential in subemployment, i.e., the combined proportion of those who are either unemployed, discouraged workers, involuntary part-time workers, or low-paid heads of families. Despite the economic gains of the past decade, almost 30 percent of the blacks in urban areas were subemployed in 1972, compared with less than 10 percent of all whites.

One of the most disturbing trends during the past decade was the continued deterioration in the labor market experience of black youth. Black teenagers experienced rates of unemployment of 25 percent and above throughout the decade, and withdrew from the labor force in alarming numbers. The dramatic decline in labor force participation among black youth greatly exceeded the experience of young whites and approached a magnitude difficult to explain in terms of the rise in school attendance among black teenagers.

II. Interpretation of the Trends

A survey of the economic literature reveals a general consensus that the relative status of blacks, especially the more educated persons, increased significantly during the past decade. Moreover, studies by most of the researchers confirm the concentration of gains among those who entered the labor market after 1965 (see F. Welch, W. Vroman, R. Freeman, R. Hall and R. Kasten, D. Bell, and J. Gwartney). A variety of data sources have been examined in the research including the decennial census, Current Population Survey, Continuous Work History Sample of the Social Security Administration, the 1967 Survey of Economic Opportunity, and the National Longitudinal Surveys from the

Parnes project at Ohio State University. Some of these data were not available for research before the 1960's.

Although the economic researchers agreed that the relative economic status of blacks had improved, they articulated competing hypotheses on the major reasons for the significant increase in the black/white income differential that had been relatively constant for much of the pre–1960 period. Economists also differed in their views on the source of continued black/white disparities in income and employment. A high level of economic activity, particularly in the latter part of the 1960's, the improved quality of education for blacks, and the reduction in labor market discrimination were identified as the major determinants. Since earnings gains were larger than what might have been expected from tight labor markets, the debate centered on the relative effects of education compared with the implementation of fair employment laws in generating the observed trends.

One optimist hailed the "collapse in traditional discriminatory patterns" and argued that the increase in black incomes during the post–1964 period was influenced primarily by the antidiscrimination efforts of the federal government (Freeman). On the other hand, O. Ashenfelter and J. Heckman, analyzing data on 40,445 establishments reporting to the U.S. Equal Employment Opportunity Commission, found that black male employment increased by only 3.3 percent more in firms with government contracts than in those with no contracts between 1966 and 1970. This difference, statistically significant at the 1 percent level, suggests that antidiscrimination activity exerted much less impact on black employment gains than estimated by some researchers (Freeman, Hall and Kasten, Welch).

At least three secondary issues raised by these studies deserve a brief comment. In cross-sectional and trend analyses several researchers found evidence that the relative income gains for blacks in the South improved markedly after 1966. In a study of black employment in the South, Ray Marshall and a team of investigators found that the South's traditional institutions including institutionalized discrimination are being eroded by forces associated with industrialization and urbanization. However, the relative gains made by blacks in the South did not alter the fundamental imbalance between black and white employment patterns. Even after the noticeable progress, blacks were two to three times as likely as whites to be clustered in low-paying operative, laborer, and service occupations (Marshall and V. Christian).

Other researchers (S. Masters, A. Van Adams and G. Nestel, L. Weiss and J. G. Williamson) were concerned about the role of migration in improving the economic position of blacks. They argued that black migrants to metropolitan communities in the North had higher incomes and less unemployment than blacks born there. "Young blacks reared and educated in the urban ghettoes of the non-South seem likely to pay a considerable premium for this environment in terms of subsequent earnings" (Van Adams and Nestel).

Educational advancement among blacks seemed to generate significant gains in employment and earnings, but the evidence does not suggest that education alone holds the key to economic equality. Although black income increased progressively with education, the marginal gain in income associated with additional increments of education appeared somewhat less for blacks than for whites. Moreover, with the black/white income ratio for males falling with increased education, the potential for improving the relative economic position of black men through increased schooling was somewhat limited. Over the decade, it appears that increased educational attainment favored black women more than black men (Freeman, Hall and Kasten, Vroman).

Another area of interest pertaining to human capital considerations is the impact of manpower programs on black economic progress. Blacks were very prominent participants in the phalanx of manpower programs initiated during the 1960's, and accounted for about 46 percent of the 8.9 million program enrollees recorded between 1965 and 1972. Blacks, however, were disproportionately concentrated in the programs which emphasized objectives other than the acquisition of marketable job skills. Perhaps as a result, the limited data on economic impact by race generally indicate that manpower programs had a very small effect on the relative employment and earnings position of blacks (C. Perry et al.). Further, the limited gains generated by the programs seem more the result of improvements in participant employment stability than in greater access to higher paying jobs.

In order to place the record of gains and contributing forces in clearer perspective, the following comments may be useful: (1) Despite past increases in black occupational status and earnings, large disparities still remain. Such gaps are evident throughout the labor force, but are especially acute among black youth and among prime age black males, whose labor force participation has declined at an alarming rate. (2) The increase in the relative economic status of black women can be considered dramatic only in relation to the restrictions placed on the upward mobility of white female workers. As indicated by Patricia Gurin, a social psychologist, "the normative stance in social science in which black men are compared to white men and black women to white women has contributed to the view that black women are somehow better off than everyone except white males." This bias obfuscates the reality of the black woman's economic position which is at the bottom of the income pyramid. (3) Increased investment in the education of blacks is a necessary but not sufficient condition for reducing the black/white income differential. Institutionalized discrimination is both subtle and pervasive and affects access to jobs, training, and promotion opportunities, thereby constraining the maximization of the black income-earning potential.

In regard to human capital investment policies, it would not be correct to conclude that manpower training programs have no role to play in increasing the relative status of blacks. Instead, it would be more accurate to say that the programs most likely to benefit blacks are those which emphasize the acquisition of marketable job skills. Even these programs, however, are unlikely to be effective if they are not linked to antidiscrimination activities. (4) Aggregative policies designed to stimulate full employment and tight labor markets have been necessary for black economic progress, but have been insufficient to produce economic equality. Some blacks register significant gains in an environment of strong labor demand while many others are left behind in a residue of unemployment, underemployment, and poverty. Among those who seem least affected by tight labor markets are black youth and inner city residents (P. Wallace).

At this point it might be appropriate to speculate on the potential effects of the current economic problems on black income and employment. Because black employment deteriorates more rapidly than that of white workers during an economic decline, it is quite likely that blacks may experience a reversal of the relative economic gains achieved in recent years. Economists are now predicting a rise in unemployment that will exceed the level attained at any time during the postwar period. If both the depth and duration of the current recession come close to the consensus projections, the fragile gains of blacks during the 1960's may be lost.

Such a pessimistic prognosis may be warranted for the following reasons. First, a deep recession will markedly worsen the position of lower-income blacks who typically receive an even smaller proportion of total money income than do lower-income white families in periods of reduced economic growth. Second, the position of black youth may well become intolerable as even larger numbers withdraw from the labor force in response to the inability to find jobs. This development will further reduce black family income and truncate the human capital improvement that occurs when young people receive on-the-job training. Third, a deep recession will, by its very nature, influence a wide spectrum of industries and occupations and will adversely affect employees with many years of seniority. For this reason, the current economic conditions may be more threatening to black progress than the relatively mild recessions of the past two decades when the average unemployment rate remained below 6.0 percent. In the current environment, it would not be unlikely to observe occupational downgrading and increased competition across education groups that may adversely affect black employment in the lower entry level white-collar jobs[1] where blacks made significant gains since 1965.

Finally, rising unemployment and the resulting increase in job competition may affect the pursuit of affirmative action and equal job opportunity. As the recession deepens, the conflict between equal opportunity and job security will generate great pressures on the personnel practices of firms in a wide range of industries. Even though antidiscrimination activity will undoubtedly continue, the direction and intensity of such efforts will certainly be affected by the political realities imposed by worsening economic conditions.

In conclusion, economists should be encouraged to continue their examination of the relative economic status of blacks in large part because economic research may provide support for urgently needed policies for moderating the degree of income inequality. It is also necessary to undertake additional research on the status and progress of other racial and ethnic minorities in the work force. Despite the lack of consensus on the relative influence of different types of public policy, it is clear that a variety of policies must be pursued simultaneously. Continued improvements in the quantity and quality of the type of economic research initiated during the 1960's on racial inequality will contribute significantly to a clearer notion of the proper mix and linkage of public policies required to achieve economic parity for racial and ethnic minorities.

Factors Affecting the Future Economic Prospects of Minorities

By DAVID H. SWINTON*

This paper discusses the general characteristics of a market economy that determines the future prospects of minorities. We are principally interested in the long-run implications of automatic market processes for the economic position of minorities. We will give only brief consideration to the role of nonmarket factors. The principal conclusion of our analysis is that the market processes will not lead to automatic improvement in the situation for minority groups. We further conclude that the likely future scenario is for slight deterioration in the minorities' relative position if the market process is left alone. And finally, we conclude that sociopolitical factors can be expected to intervene into the market process with undetermined results.

The overall structure of economic well-being in a private property market economy is determined by the technical and organizational characteristics of productive activities and the stock of both human and nonhuman resources. For any given structure of productive activities and resources, we can postulate the existence of an equilibrium distribution of economic well-being. The market mechanism should automatically bring about the equilibrium distribution. Our discussion concentrates on the factors determining the distribution of this equilibrium well-being between majority and minority groups.

Most economic theorists would probably accept the proposition that a market economy could reach an equilibrium without full employment and, in fact, without even guaranteeing survival of all of its members. Moreover, it is also the case that our modern economy is characterized by differentiated opportunity structures. The existence of unemployment and differentiated opportunity structures creates the possibilities for relative differences in individual economic well-being in equilibrium.

Since capitalistic societies are characterized by the selfish pursuit of individual self-interest, individuals can be expected to utilize whatever techniques are available to attain the higher valued opportunities. Thus, individuals have an incentive to enter coalitions to influence the personal allocation of opportunities, where a basis for stable coalitions exists and where the benefits from coalition membership are greater than the cost. In complex, multiracial and capitalistic societies, racial or ethnic coalitions arise to influence the allocation of benefits whenever clear group identifications exist and the potential power of one group is greater than the potential power of the other.

Thus, at any point in time, the relative and absolute position of the minority will be determined by three principal factors: the level and structure of opportunity in the society, the distribution of resources, and the extent of discrimination. The level and structure of opportunity determine what is available in the given society. The distribution of resources determines an individual's technical suitability or eligibility for the available opportunities. And discrimination is a part of the process which allocates the scarce opportunities.

---

* State University of New York, Stony Brook.

Changes in the position of the minority over time result from changes in these basic factors. We shall discuss each of these factors in turn while holding the others constant.

The degree of inequality in the structure of opportunities and the quantity of opportunities relative to the population are the first factor. If there are wide disparities between the rewards of various opportunities, the minority will be relatively worse off. On the other hand, in structures characterized by narrow differences in rewards, the minority-majority differences will be less. Likewise, where there are few opportunities relative to the population, the minority will suffer a relatively high level of unemployment. Expansion of opportunities at rates faster than the rate of growth of resource populations will cause expanded employment of minority-owned resources. Failure of opportunities to expand as fast as populations will cause relative and absolute unemployment of minority resources. Increases in the range and variance of value will lower the relative value of minority-owned resources.

The significant question is whether the economy tends to create, through the automatic workings of the market, the factors which would lead to relative improvement in the minority position. Any automatic tendencies to cause convergence in differentiated reward structures or to create full employment of resources will improve the minorities' relative welfare over time.

Although full employment was frequently assumed in the past, the economic processes which would bring it about were never clear, not even in the theoretical perfectly competitive economy, if the least bit of realism was introduced. The wage rate that would bring about full employment may not be above subsistence and, in fact, may not even be nonnegative. Moreover, in models where one recognizes the relative fixity of capital/labor ratios and the limitations of effective demand, the likelihood of a less than full employment equilibrium at any given level of resource and income is apparent. In the real world there are also numerous barriers to resource mobility that create relatively inflexible resource prices, especially in the downwards direction. This inflexibility is relatively immune to the existence of unemployed resources. Yet it is the flexibility of resource prices that is at the heart of the market's automatic adjustment capability.

There may actually be a tendency to unemployment and underemployment of resources given the investment propensities of capitalists. Automation, for instance, clearly must tend to increase the unemployment of human resources, other things remaining equal. The greater use of large-scale techniques with large initial requirements for capital also clearly lowers the value and increases the unemployment of resources employed in small-scale activities. Increasingly, important resource shortages and limitations of effective demand may also tend to increase unemployment of resources. Increased international competition and the investment propensities of multinational corporations also limit the employment of domestic resources. The possibility of increasing resource unemployment seems almost unavoidable when we combine these demand side changes with current sociological trends, which are tending to increase the relative supply of human resources.

In a competitive economy, rates of return to equivalent resources in different employments would tend to equality over time through the workings of the arbitrage processes. This would cause convergence in the net value of employed minority and majority resources. However, deviations from perfect competition that interfere with resource mobility prevent the arbitrage processes from operating effectively. Given such imperfections, which certainly are characteristic of the American economy, the market cannot automatically eliminate value differences. Thus, such differences can be expected to continue over time if the market is left to its own ways.

The second major factor influencing the relative well-being of minorities is the structure of resource ownership. The larger the proportion of resources owned or controlled by the minority, the better off is the minority. As before, our principal interest is in the implications of market operations for the dynamic path of the resource distribution.

If there were no extra market intervention, there would be little reason to expect greater equality in the racial distribution of resources. The accumulation of resources depends upon savings, and since savings is a function of current income, which in turn depends upon current resources ownership, it is clear that those who currently own the most resources will do the most savings.

The distribution of human capital over time is probably not as directly tied to the initial distribution because human capital in general cannot be inherited. Moreover, there is a large-scale public role in the creation and distribution of human capital through the public school system. Nonetheless, there is still a strong tie between initial wealth and the ability to attain human capital since much human capital, especially high quality types, must be purchased through the private market. Even within the sphere of public supply, there are quantitative and qualitative differentials in human capital, and the access to the better qualities here also depends upon initial wealth. Much human capital is acquired in conjunction with the pursuit of various opportunities, so that the distribution of this type of capital is subject to the same considerations as the distribution of opportunities.

However, over time we cannot expect the slight equalizing tendency in human capital to be sufficient to cause significant reduction in current disparities in overall resource ownership. The recent trends respecting racial differentials in the quality of human capital acquired in the public schools would indicate that part of the quantitative gains has been offset by qualitative deterioration. The public's willingness to expand the public role sufficiently to eliminate both the quantitative and qualitative differences which remain appears limited.

We must conclude, therefore, that there are no automatic forces operating in the market to eliminate resource differences over time. In fact, the automatic tendency of the market would be to increase differences in resource ownership. This tendency is partially offset by public activity especially in the provision of human capital development. However, the overall impact of this activity is limited and in any event it is not automatic. Barring additional intervention, the market will not significantly reduce the disparities in resource ownership. This factor, therefore, cannot lead to improvement in the well-being of minorities over time.

The final factor influencing the economic future of minorities is the extent of discrimination. The impact of this factor on the well-being of minorities at any point depends upon the intensity of discrimination. The more intense the discrimination, the worse off is the minority. The intensity of discrimination will depend upon the cost and benefits of discrimination. The greater the benefit, the greater the discrimination, and the greater the cost, the smaller is the level of discrimination.

At any point in time, the benefits will depend upon the level and structure of opportunity and the racial distribution of resources. The greater is the quantity of resources held by the minority, the more the benefit from discrimination. Similarly, the more structural inequality and the lower the level of opportunities, the more benefit there is from discrimination. The cost also depends fundamentally on the distribution of resources and the level and structure of opportunity. Here the greater the amount of resources held by the minority, the higher the cost of discrimination. However, the lower the level of opportunities and the greater the structural inequality, the less costly is discrimination.

Here again we are also interested in the dynamic impact of automatic market forces. To reduce discrimination, these forces would have to reduce the benefits of discrimination relative to the cost. However, both the benefits and the cost of discrimination are connected to the market through the distribution of resources and the structural characteristics of production. Therefore, the economic incentive to discriminate can only be reduced over time by changing these underlying factors. We have already seen that there are no identifiable automatic forces working toward greater equality in the distribution of resources or less differentiation in the structure of rewards. These factors, therefore, cannot be counted on to lower discrimination.

However, there could well be more inequality in the distribution of resources. This would lower the cost as well as the benefit from discrimination. Only if the benefit is lowered more than the cost will overt discrimination lessen. However, this will not lead to improvement in the situation of minority groups because the lower discrimination will be offset by lower relative resources.

The dynamic paths taken by the economy during this century have worked in two directions at once. Technological change in southern agriculture has tended to increase the relative unemployment of minority resources which were heavily engaged in low-valued agricultural pursuits at the turn of the century. However, the rate of expansion of opportunities in the nonagricultural sectors was sufficient to absorb a large proportion of the minority resources that could not be employed in agriculture. This not only prevented the unemployment of minority resources, but also increased the absolute and overall relative value of minority-owned resources. However, these migration processes have led to deteriorating relative value of minority-owned resources in regions outside of the south since 1950. Moreover, these intersectoral and interregional arbitrage possibilities have practically vanished, and the rate of expansion of opportunities in the society as a whole has not been sufficient to absorb all of the resources in the past couple of decades. As a result, minorities find themselves increasingly unemployed, underemployed and outside of the labor force.

Moreover, throughout this period the overall inequality in the value of opportunities has not significantly narrowed. And during the past twenty-five or so years, the degree of inequality in the structure of opportunities has probably increased. This fact alone should be expected to lead to relative increases in the gap between the value of majority and minority resources.

We can therefore draw the overall conclusion that automatic market adjustment processes will not tend to improve the relative situation of the minority in the future. The three determining factors mentioned *could* lead to improvement, stability, or deterioration since all three types of changes would be consistent with market equilibrium and would be produced under the appropriate circumstances. There is no automatic tendency for the economy to produce either result. In the current situation, however, the dynamic implications of the market process for the structure of opportunities and the distribution of resources imply at best slight deterioration in the relative well-being of minorities in the future. Thus, if the selfish maximization of individual welfare continues to be the prevailing behavioral norm, the free market, left to itself, will attain an economic equilibrium path which preserves the relative minority-majority welfare disparity.

This economic equilibrium, however, will not necessarily be consistent with overall sociopolitical equilibrium. The continued existence of relative disparities could lead to the intervention of noneconomic factors into the equilibrium determination processes as a result of efforts by the minority to reduce the disparities. Thus, efforts would be made either to alter the three determining factors or to alter the distribution-determining processes, i.e., change the economic system.

Noneconomic action can be carried out either by public authorities or private individuals and coalitions. In the latter case, it is the minority that will act since it is the minority that will be dissatisfied with the free market solution. The success of minority efforts will depend upon their ability to reduce the benefits or raise the cost accruing to the majority as a result of the current equilibrium. The idea is to introduce noneconomic cost-raising factors to the degree where it becomes optimum for the majority to alter the status quo solution. Such alteration involves reducing discrimination, redistributing resources or altering the structure of opportunities.

It is not clear that there exists a set of noneconomic actions available to the minority that will move the status quo equilibrium as far as desired. It is probably the case, if parties are rational, that there is a set of actions that will move the status quo equilibrium in the desired direction. Obviously, however, noneconomic actions involve cost of some kind. Moreover, the majority may be able to respond with action short of altering the status quo equilibrium. However, this action itself must involve cost so there must be a negotiating range. Whether or not there is movement in the desired direction will depend upon the relative strengths of the two parties. One should also note that it is possible that such tactics could lead to a lower status quo equilibrium for the minority. However, pursuit of these points is beyond the scope of this paper.

Moreover, it is also not clear that conflict situations such as the above can be treated with the limited concept of rationality implicit in what we have done. *Discrimination practiced over long periods of time develops its own dynamics.* Thus, even though the narrowly defined economic cost of discrimination exceeds the economic benefit of discrimination, the process may continue for some period of time, either because of expectations of future benefits, failure to perceive the changed situation, or the existence of noneconomic benefits. Failure to perceive the loss in net benefits will be particularly likely when, as is the case with discrimination in the United States, the benefits and cost are distributed differently. Moreover, the public authorities may absorb most of the cost of maintaining the status quo, further hiding the cost from individuals. Thus, individuals will not associate the benefits with the cost, or will believe that the cost can be reduced without reducing the benefits.

Rational public authorities might also be induced to intervene in the market equilibrium process if the disparity prevents the attainment of social equilibrium. The intervention by the public authority will be brought about by its responsibility to maintain the social equilibrium where deviations from social equilibrium either threaten the social stability or the social welfare. The inducement results from the fact that minorities will favor alteration of the status quo equilibriums along racial lines and majorities will prefer maintenance of status quo equilibriums. This results in conflict as discussed above. The public authority must undertake activities that reduce the conflict. This can be accomplished in at least two ways. The first way is to suppress the minority cost-raising activity. The second is to alter the status quo equilibrium to reduce the majority-minority disparity. This latter action may give rise to majority cost-raising activities.

The action taken by the public authority will depend upon the objectives of the public authority, which in turn follows from the processes by which objectives are reached and the relative weight of minorities in these sociopolitical processes. This, however, is far beyond the scope of this paper but it is clear that we can by no means assume that public action will be favorable to the minority.

In any case, in view of the fact that the market will not automatically cause improvement, any chance of assuring improvement in future prospects for minorities lies in some kind of sociopolitical intervention in the market processes. The phenomenon of discrimination is itself a social intervention into the determination of market equilibrium. There is nothing sacred about the market equilibrium which itself is just the outcome of a particular set of sociopolitical processes. Therefore, additional intervention can certainly be justified whenever the outcome is undesirable. In view of the difficulties inherent in changing status quo solutions, it should be apparent that the minority must be willing to make sacrifices and persevere in order to improve its future prospects.

DISCUSSION

Ronald L. Trosper, University of Washington: My mandate here is to extend the three papers to Native Americans. Since this is a large task for a brief space, I will focus on main points. I begin with general remarks and end by applying them as brief criticism of the papers just presented.

One should expect that the forms of discrimination would vary across minority groups during a given year and during a given century. Some differences between blacks and Native Americans are so important that policies or predictions based on intuition developed with current models of discrimination against blacks lead to serious error when applied to Native Americans. One error is to omit land and sovereignty as variables. Another is to fail to examine the full range of policies open to the majority when they discriminate.

Because Native Americans have always owned large amounts of land and still do, an exclusive focus on labor markets is incorrect. The nature of property law and the limitations on it are different for land, physical capital, and human capital. As a result, the benefits and costs of different forms of discrimination change as compared to blacks. Hence, the preferred forms of discrimination also change.

For Native Americans, one must emphasize the benefits of sovereignty and focus upon the problems which tribal governments have protecting and utilizing their constitutional status. Personal sovereignty, or freedom, is emphasized for blacks. Governments should be able to tax and to control property law among individuals within their jurisdiction, including whites who settle upon confiscated lands. Native Americans ruled themselves originally and have attempted to adjust their political institutions in order to retain control over internal affairs, in spite of becoming politically subordinate to the United States government. I believe that the power to tax and to write civil and criminal law are important economic variables.

Although land and sovereignty are key variables, the sad fact is that Indians have suffered continual erosion in their possession of both. With more space, I would elaborate the nature of the erosion. Instead, I shall indicate how these two variables change models of discrimination.

Suppose a tribe owns land whose products such as timber, fur, buffalo, minerals, or oil can be transformed into capital with little net borrowing. Suppose, further, that historically the tribe has successfully administered property rights in land among its members, with exclusive use-rights but a system of inheritance different from the American norm. Suppose, also, that it can tax all, white or Indian, who live within a designated boundary. Then questions about segregation in work places or residences are not major. More important are questions about trade with outsiders, immigration and intermarriage, and the ability of the tribe to prevent confiscation of land and sovereignty.

The federal government has always had a conflict of interest in its chosen role as protector of Indian property rights. American politicians and bureaucrats perceive a choice in the implementation of discrimination between trade methods and confiscation methods. Let us examine briefly the benefits and costs which affect the choice. Thinking in terms of centuries, the benefits of confiscation vary with the price of land, with land classified by type of natural resource. The costs depend upon other factors. For instance, in 1974 the strength of the sympathy vote is important. In 1874, the availability of rifles, ammunition, and horses mattered. In 1774, the strategic relationships between a tribe and the British mattered. At times, the American government has preferred trade to confiscation after examining the benefits and the costs.

Finally, I must emphasize that Native Americans are very diverse. Our cultures are different from one another, both aboriginally and in the type of borrowing from Europeans. Further, the relative success in retaining land and sovereignty varies greatly among tribes. Those who wish nationally valid generalizations risk error should they try to apply the same analysis to the Native Americans of Alaska, New York, Montana, and Washington; these four states, for instance, each represent four different legal situations.

Currently, the short-term outlook for Native Americans is good. A year ago Congress restored the sovereignty of the Menominee Indians of Wisconsin by reversing the abolition of their reservation. Congress rescinded a law passed in 1954 and implemented in 1961. In 1971 Congress returned some land to the Taos Pueblo in New Mexico. The Yakima and Warm Springs Reservations have also had land returned. How long will this policy last? Native Americans do not now assume that their position is secure. The federal government currently finds a trade policy preferable to a confiscation policy. Perhaps the benefits and the costs which led to this decision will change again in the future.

I disagree with the previous speakers in their choice of variables to exclude when discussing future prospects. When David Swinton spoke of resources, he usually meant human capital, not land or even physical capital. He did not discuss sovereignty. If he is right to conclude that the market currently has no inherent tendency either to lessen or to increase inequality, I would suggest examining the potentials of confiscation. If he had concluded that the market currently tends to lessen inequality, I would have asked if confiscation was imminent.

Robert Fogel and other scholars examining slavery recognize the choice between money and force to accomplish the transfer of resources to whites from nonwhites. As in the North, whites in the South displaced Indians from their land before 1860. Those Native Americans joined others in Oklahoma. There they retained substantial sovereignty until early in this century when they endured another onslaught of confiscation and were finally reduced to poverty.

Bernard Anderson and Phyllis Wallace also focus exclusively on labor markets. I would emphasize that Native Americans experience high levels of unemployment and limited access to high-paying occupations in addition to the problems I referred to earlier. Policy based on exclusive attention to these employment problems, however, leads to serious errors. It is for this reason that I stressed land and sovereignty in these remarks.

Many of you may feel that these variables are also important for other minorities. Although I agree, the diversity among Native Americans makes me expect much variation in the manner in which land and sovereignty affect other minorities.

DANIEL FUSFELD, University of Michigan: I was asked to comment on the last two papers. I did not obtain Robert Fogel's paper until this session, so I cannot really comment on it.

Regarding the last two papers, by Bernard Anderson and Phyllis Wallace, and David Swinton, I did not like either one, in many ways, for much the same reasons. They both stay within the establishment, neoclassical economic framework. That is just the wrong way to approach the problems of minority groups, particularly those of blacks, Indians, and women. The neoclassical model assumes continuity in labor markets and unified labor markets; it assumes even adjustments across the board, and it excludes exactly the kind of relevant variables that Fogel, for example, included in his analysis. The key point that Fogel makes is that the viability of the large-scale plantation in the South before the Civil War was due to a high degree of institutionalized exploitation of black labor. It was not because large-scale plantation agriculture was more efficient than the small farm. If it were more efficient, we would have had a recurrence of large-scale plantation agriculture after the Civil War, which we did not get. That mode of economically successful operation was made possible by exploitation, by the use of force and power to exploit blacks.

Another point about Fogel's analysis illustrates why the neoclassical analysis cannot help us understand exploitive patterns of behavior. Those plantations were efficient as economic units. People running them sought to maximize their welfare, as did the slaves, given the opportunities available. Yet it was far from a social optimum. The central problem involves the basic institutional parameters within which the profit-maximizing activities of individuals or other economic units are carried on.

Let me develop this point specifically with respect to the other two papers. Anderson and Wallace present a view of the economy as a whole. The welfare of blacks and other ethnic groups is said to have improved during the 1960's, and to have deteriorated maybe in the few years since then. The problem here is—which blacks are we talking about? Do we consider the black man who picks up the trash in front of my house every week, or the black psychiatrist who lives next door? We may very well hire black, professional economists to teach students at the University of Michigan or other institutions of higher learning. This may have no impact whatsoever on the way of life of that poor guy who picks up the trash. Yet, hiring the black economist to teach in the university may statistically pull up the average. Thus, we must not look at just the overall view of the labor market, confining ourselves to averages. We need to go beyond what Anderson and Wallace did and look at it in terms of the cyclical aspects, prosperity versus not so prosperous times, and rapid growth versus stagnation. We also have to consider what is transpiring within the minority community. There is good reason to believe, on both empirical and theoretical grounds, that, while the averages showed an improvement in the condition of blacks taken as a whole during the 1960's, there was still a deterioration in the economic and social condition of blacks living within the inner city ghettos. It is that kind of a question, it seems to me, that we have to get into in much greater detail.

Turning to Swinton's paper, the line of argument was basically this: first, the economic position of minority groups relative to the majority seems to have stabilized within a new economic equilibrium that has emerged after the urban revolts of the 1960's. Second, there is little reason to believe that economic forces alone will eliminate the present disparities that seem to have stabilized. And finally, the only alternative is political action that will widen opportunities, redistribute resources, and reduce discrimination.

I agree fully with that line of argument, but I do not think Swinton properly analyzed why economic forces alone will not be able to eliminate the present disparities. He was basically saying that disparities between the races are due to disparities in the level and structure of opportunity, and those disparities are created by discrimination against minorities. Likewise, there are disparities in the distribution of resources which lead to further economic disparities, but those are themselves related to discrimination. The entire argument is circular: the economic system alone will not correct the problem of discrimination because of discrimination.

Another part of his argument is that there are inflexibilities and imperfections in the way in which the market functions; many of the disparities between minorities and majorities are the results of these imperfections. If I might step out of my normal abode and become an apologist for the economic system, the answer is obvious: all we need to do is make a few marginal adjustments in the economic system to get rid of the imperfections; and we then need to change the majority by educating it a little bit to get rid of its propensity to discriminate; and maybe at the same time provide some more human capital to minority groups; and then let the economic system slowly and gradually but completely eliminate the disparities. His argument does not show that the economic system, as such, will fail to terminate the inequality. It is the things wrong with the economic system that are at fault. A little action here and there can set things right. The nonclassical argument remains.

I would like to cast the discussion in a completely different framework. Returning to Fogel, we can state that coerced labor has always been a feature of the American economy, particularly with regard to a variety of minority groups: blacks, Indians, and women, in particular. With respect to blacks, before the Civil War there was the system of slavery, followed after the Civil War by a system of debt-tenure in southern agriculture in the sharecropping system, in turn followed after the breakup of the sharecropping system with ghettoization and crowding of blacks into menial occupations. The economy moved from a legally sanctioned form of coercion to a quasi-legal form, to what is now essentially an economic and social form of coercion, far more subtle in its operation, all three having the key economic characteristic of excluding the minority groups from some opportunities which then enables them to be exploited in the occupations or employments into which they are crowded by slavery, sharecropping, or ghettoization. If this is the economic history of blacks and other minority groups—in this case, particularly blacks—note one very fundamental point: each transition was marked by a major social, political, or economic trauma following the period of stability and viability of the particular forms of coercion of labor that existed. Slavery as a form of coerced labor was ended with the Civil War, certainly a traumatic event. Sharecropping and its system of debt-tenure was ended by a series of economic disasters starting with the boll weevil, including the impact of the Great Depression, and ending with the mechanization of the labor process in southern agriculture. This series of drastic events coming from essentially outside the labor system itself was much more traumatic for blacks than for any other group.

The question is then raised: given the proposition that the present system of ghettoization and coerced labor has been stabilized in the institutional structure, what kind of traumatic economic or political event or set of events is going to change it? I really agree with Swinton. He is right. The present system has been very largely stabilized. It is not going to be broken by economic evolution. The kinds of things that are going to break it, however, it seems to me, are going to be far more drastic than, as he suggests, political action by the minority groups themselves.

THE HUMAN CAPITAL APPROACH: AN APPRAISAL

Human Capital Theory: Education, Discrimination, and Life Cycles

By FINIS WELCH*

The most important point I can make in assessing contributions of human capital theory is that it is a tool for analysis and is neither a religion nor a shrine. Like any other analytical tool, we use it when it simplifies interpretation of complex phenomena and reject it when it conceals more than it reveals. Much of the burden of defining "what human capital theory says" has been assumed by detractors who, in many cases, offer caricatures in lieu of characterization. Omissions and abstractions are criticized without regard for the context in which assumptions are made and without reference to the predictive power of simplifying assumptions. Human capital theory is based only on the presumption that labor skills or market perceptions of skill are both durable and malleable. This, surely, is not a philosophy of labor markets.

Three topics are discussed here. They do not represent a comprehensive view, but are each part of the overall question of income distributions and have each absorbed the attention of many working with human capital theory. The topics are: (1) wealth distributions and life-cycle earnings profiles; (2) sources of income returns to schooling; and (3) race differences in income. My objective is to describe what I think we have learned about these phenomena as well as to point to the most important unsettled issues.

I. Wealth Distributions and Life-cycle Earnings Profiles

The popular theories of G. S. Becker (1965), Y. Ben-Porath, J. Mincer (1962 and 1974), and S. Rosen view the distribution of labor earnings over a worker's career as endogenous to his own behavior. Although objective functions are usually described in terms of full life-cycle utility, in application the objective is maximization of discounted earnings. Work serves a dual function: it contributes current earnings and affects future productivity. Workers are viewed as determining the rate at which current earnings are sacrificed in light of future prospects. Since the period over which earnings can be recouped declines as age increases, the value of currently foregone earnings declines with increasing age. This prediction of declining investments with increasing age is the most consistent feature of the standard theories, although they also allow the rate of investment in future productivity to depend on the extent to which previously acquired skills enhance or detract from the ability to continue the skill acquisition process. Because investments decline with age, these theories invariably predict observed earnings profiles that possess negative second derivatives over much of the worker's life.

We can lament the fact that none of these theories have been reduced to simple, i.e., empirically tractable, and identifiable functions describing lifetime earnings. Such functions would be helpful in evaluating impacts of policy options ranging from income maintenance programs to subsidized training and unemployment insurance. Yet the lack of available data for lifetime earnings profiles of individuals not only limits us in identifying such functions, but more importantly, it prevents evaluation of the quantitative impact of investments in human capital in shaping earnings. Without time series observations of individuals, we have turned to analyses of cross-sectional data which compare different people of different ages.

---

* University of California at Los Angeles and the Rand Corporation. I am indebted to Dennis DeTray and James P. Smith for comments during the construction of this draft.

Thanks largely to Mincer (1974) we have evidence that in the cross-section, earnings profiles appear very much *as though* they result from investment processes like those described above. This is true not only of mean earnings at various ages for persons of similar schooling, race, etc., but earnings variance among individuals appears to exhibit U-shaped age profiles. The variance idea is central to contrasts of wealth, i.e., discounted lifetime earnings, distributions with earnings distributions at various points in the life-cycle. Suppose that within a given schooling-race cohort individuals faced with differing ability, tastes, access to investable funds, etc. elect differing time shapes for their own earnings profiles. Early in the career, heavy investors will have low earnings (relative to their alternatives) which are subsequently compensated by high earnings. Given a distribution of investment profiles among individuals, it seems reasonable to expect age-related earnings profiles to be dominated by differences in investments early in the career. But in the early phases, earnings variances will decline with age as investments and returns on earlier investments tend toward zero sum. Still later, variance will rise as returns to earlier investments dominate. It is this view which leads Mincer to predict U-shaped age-earnings variance profiles, and these predictions are confirmed in his analysis of the 1960 census.

At any point in the worker's career, earnings can be viewed as the sum of two terms. One corresponds to his permanent income—the average annual equivalent value of his discounted lifetime earnings. The other, his net investment, is the sum of currently foregone earnings as investments in the future and the realized return on his past investments. This second term has zero discounted value over the life cycle, and although it may add or detract from earnings variance among individuals at any point, it plays no role in comparisons of lifetime wealth. Unfortunately, available data permit only guesses about the numerical import of that part of earnings variance at a point in the career which is fully compensated over the life cycle. Lee Lillard has analyzed data from the National Bureau of Economic Research (*NBER*)-Thorndike sample. It contains observations of approximately 5,000 individuals with earnings at five career points. Lillard first estimates a relatively unconstrained function and finds, as did Mincer, that the shape of the estimated earnings function is consistent with the investment view. He next contrasts a measure of average annual earnings variance with alternative estimates of variance in the distribution of discounted lifetime earnings under two extreme assumptions about the life-cycle persistence of residuals observed for individuals. The lower estimate assumes that residuals are purely transitory and under this assumption the coefficient of variation for discounted lifetime earnings is only about one-fourth of the coefficient of variation for mean earnings.[1] The upper bound assumes that residuals are completely persistent throughout the worker's life. Under this assumption, the coefficient of variation for discounted earnings is 40 percent greater than the corresponding measure for mean earnings. Lillard felt that, with only five data points for each individual, he was unable to make more refined statements about the autocovariance structure of individual residuals from the estimated earnings structure. Nonetheless, his estimates serve as an indication of our ignorance, for the range between 0.25 and 1.4 is large and we have little information about the role of compensating variations in observed earnings distributions.

---

[1] Lillard's lower estimate is not a lower bound since it is possible, but unlikely, that residuals from his estimated equation are not transitory at all but are fully compensated within the life cycle. In this case, the coefficient of variation for wealth is roughly 10 percent of the coefficient of variation for annual earnings.

Mincer's prediction of a U-shaped age-earnings variance profile hinges on the assumption of an "overtaking age" that has reasonably small variance among individuals in a cohort. The overtaking age is defined as the age at which observed earnings are equal to average annual equivalent earnings for the discounted lifetime profile. Based on the notion of a common overtaking age for members of a cohort, John Hause reports data both for Sweden and the United States which show significant negative auto-covariance among individuals. This is evidence of compensating variation, but unfortunately it has not been quantified in a manner useful for reducing the range on Lillard's bounds. It can only be taken as a hint that the upper bound may be a significant overstatement.

To me, the question of the importance of the human capital concept in interpreting differences in human wealth is closely linked to the question of the numerical import of compensating variations. Yet resolution of this question awaits either better data or more ingenious use of existing files.

II. Sources of Income Returns to Schooling

The positive association between income and schooling is well-known, but the nature of the underlying mechanism continues to be a topic of lively debate. The early literature of human capital assumed, perhaps blithely, not only that a causal relation exists, but that the zero-order association that corrects neither for "ability" nor "background" offers an adequate basis for calculations of rates of return and for estimates, based on these returns, of the contributions of increased schooling levels to economic growth. Recently a number of authors have questioned assumptions on which the early calculations were based. The dissent is wide-ranging and includes questions of the role of ability and family background and the nature of acquired skills. It also includes the fundamental question of whether schools contribute directly to market skills or only serve an identifying or screening function. My purpose is to summarize some salient features of this discussion along with the available evidence.

It seems noteworthy that the fundamental notion of human capital, of foregoing current income for the prospect of increased future earnings, assumes only that the schooling-income association is not spurious. As such, it is fully consistent with the screening view that schools primarily identify preexistent skills and with the view that market skills are produced in school. If marketable skills are produced in school, it does not matter from a positive perspective whether the skills are predominately affective as H. Gintis posits or whether they are cognitive.

Is the income-schooling association spurious? Here, on the basis of available data, the answer is no. There are numerous available studies that consider earnings as functions of schooling, measured ability, and family background. These studies consistently show that the partial relation between income and schooling is weaker, i.e., implies lower returns to schooling than the zero-order association. While there is a wide range of reductions in measured returns to schooling that follow corrections for ability and family background, none of the estimates show a zero net return to schooling.

Briefly, consider the evidence. Gintis summarizes nine different studies in which the reduction in the schooling coefficient achieved by an ability correction ranges from 4 to 35 percent and in these studies the central tendency appears to be a little above 10 percent. E. Hanushek partitioned a large data base into 200 subsamples based on race and region of residence. The average schooling coefficient is reduced by about 15 percent by introducing an ability correction. P. Taubman and T. Wales report a 9 percent reduction in the schooling coefficient when correcting for a measure of general ability and a reduction of 30 to 35 percent when correcting for mathematical ability.

The paper by Z. Griliches and M. Mason is particularly interesting in these comparisons. Their task is not only one of assessing the sheer size of the school and ability effects, but of analyzing robustness under specifications that alternate control for factors pertaining to family background, race, and residence and then leave these controls free to vary so that their effects are captured by correlates. A unique feature of the Griliches-Mason data is that ability, the armed forces qualifying exam, is observed at an intermediate point in the schooling career—the point of entry into the armed forces. In principle, this allows identification not only of effects of measured ability on income, but of biases in returns to schooling due to a failure to correct for initial ability. Their estimates show a reduction in schooling's measured contributions to earnings of 7 to 10 percent when controlling for measured initial ability and of reductions of 13 to 17 percent when controlling for postschool measured ability. Gintis does not distinguish in his survey whether ability is measured pre- or postschool. Hanushek's measure is postschool and Taubman and Wales use a measure obtained on completion of high school for a sample in which the majority of observations are college graduates.

Just as measured ability and school completion are correlated, so are family socioeconomic status (*SES*) and schooling. As with ability corrections, most studies controlling for family background report small reductions in estimates of income returns to schooling. J. Morgan and M. David note that including variables for father's education and an index of family *SES* reduces the measured contribution of schooling to income by 12 percent. F. T. Juster reports a slightly smaller effect. And M. Carnoy (1964) using data from Mexico finds independence between computed rates of return and father's occupation. In a sample restricted to persons of very high measured I.Q. (above 135), Arleen Leibowitz finds no relation between family *SES* and income, but does find that school completion and family *SES* are positively correlated. S. Bowles, on the other hand, estimates that controlling for family background reduces the apparent return to schooling by 40 percent.

In this context, the Griliches-Mason work is also illuminating for it is not clear how the interdependence between schooling, income, and family background should be interpreted. Family background may serve as a proxy for quality of schooling and for complementarities between school and home environments or it may index access to good, i.e., high salaried, jobs for which schooling is necessary but not sufficient. If background indexes the quality of the learning environment, we would expect effects of family background on income contribution to schooling to be higher for schooling acquired while the child resides with his parents than for schooling acquired after leaving home. In the Griliches-Mason data, the school career is interrupted by service in the armed forces, and they find that by controlling for family background the income contribution of schooling is reduced by 25 percent for pre–armed forces schooling and by only 3 to 6 percent for schooling acquired after being in the armed forces.

Controls for ability and/or for family background appear to reduce the measured contribution of income to schooling but they do not reduce it to zero. The argument that the income-schooling relationships are causal remains intact.

The available literature either ignores or treats only lightly the question of measurement error. Yet I think this is a problem of considerable importance. Frankly, I find it hard to conceive of a poorer measure of the marketable skills a person acquires in school than the number of years he has been able to endure a classroom environment. My only justification for using such a crude measure is that I can find nothing better. Too, I am very agnostic about what "ability" tests measure.[2] Similar statements hold for measures of home environment. Yet as soon as we open the door to measurement error, we find a completely nebulous world in which almost anything is possible.

Consider a simple regression model of measurement error described as:

$$y = \beta_1\tilde{s} + \beta_2\tilde{a} + u \tag{1}$$

$$s = \tilde{s} + v_1 \tag{2}$$

$$a = \tilde{a} + v_2 \tag{3}$$

with the residuals or measurement errors, u, v_1, and v_2 being mutually independent as well as independent of $\tilde{s}$ and $\tilde{a}$. Here y denotes individual income, $\tilde{s}$ is marketable skills acquired in school scaled to the units of school years completed, and $\tilde{a}$ describes true initial (preschool) ability. Observations of schooling and ability, s and a, are with error, v_1 and v_2, respectively. It is easy to show that:

$$\textit{plim}\, b_{ys} = (\beta_1 + \beta_2\rho_{\tilde{a}\tilde{s}})r^2_{s\tilde{s}} \quad \text{and} \tag{4}$$

$$\textit{plim}\, b_{ys\cdot a} = \beta_1 r^2_{s\tilde{s}\cdot a} + \beta_2\rho_{\tilde{a}\tilde{s}}r^2_{s\tilde{s}}(1 - r^2_{a\tilde{a}\cdot s}) \tag{5}$$

where *plim* refers to the limit in probability, b_{ys} is the ordinary least square (*ols*) coefficient from the regression of y on s, $b_{ys\cdot a}$ is the *ols* coefficient of the regression of y on s holding a constant, $\rho_{\tilde{a}\tilde{s}}$ is the *ols* coefficient from the auxiliary regression of $\tilde{a}$ on $\tilde{s}$, $r^2_{s\tilde{s}}$ is a squared zero-order correlation coefficient and $r^2_{s\tilde{s}\cdot a}$ and $r^2_{a\tilde{a}\cdot s}$ are squared partial correlations.[3] It is assumed that $\beta_1, \beta_2, \rho_{\tilde{a}\tilde{s}} > 0$.

Under these assumptions, it is not clear, a priori, that the regression which does not correct for ability overstates the income return to schooling. It is understated (in the probability limit) by $\beta_1 (1-r^2_{s\tilde{s}})$ and overstated by $\beta_2\rho_{\tilde{a}\tilde{s}}r^2_{s\tilde{s}}$. Similarly, it is not clear that "corrections" for ability improve the estimate of β_1, the contribution of schooling to earnings. Comparison of the uncorrected, b_{ys}, and corrected, $b_{ys\cdot a}$, measures show unambiguously that (in the limit) $b_{ys\cdot a} < b_{ys}$. The correction has two effects. It reduces the overstatement from $\beta_2\rho_{\tilde{a}\tilde{s}}r^2_{s\tilde{s}}$ to $\beta_2\rho_{\tilde{a}\tilde{s}}r^2_{s\tilde{s}} (1-r^2_{a\tilde{a}\cdot s})$ but since $r^2_{s\tilde{s}\cdot a} < r^2_{s\tilde{s}}$ *it increases* the understatement from $\beta_1(1-r^2_{s\tilde{s}})$ to $\beta_1(1-r^2_{s\tilde{s}\cdot a})$.[4]

My point is that part of the recent literature seems to have evolved into a game in which we search for the set of control variables which minimize the measured direct return to schooling. I hope it is obvious from the errors-in-variables discussion that this game is not without pitfalls.

---

[2] I have summarized these objections elsewhere and will not repeat them here (see Welch 1974b).

[3] All correlations here refer to limits in probability.

[4] In this description: $r^2_{s\tilde{s}} - r^2_{s\tilde{s}\cdot a} = r^2_{sa}(1 - r^2_{s\tilde{s}\cdot a}) > 0$.

What can be said about the nature of skills associated with schooling? In this, as in most areas of economics, the data offer only a few hints. Gintis, noting that measured returns to schooling corrected for postschool ability average 80 to 90 percent of the uncorrected measures, argues that market skills associated with schooling are not the cognitive skills that tests measure. This interpretation seems valid, but due to the errors-in-variables discussion, I would underscore that the income return appears not to consist mainly of what ability tests *measure*. Elsewhere I have argued that, in dynamic environments in which abilities to acquire and decode information are at a premium, the return to schooling may partly reflect allocative abilities.

Carnoy's finding (1967) that estimated returns to schooling in Latin America are positively associated with rates of growth in real per capita income is relevant here. I have offered similar evidence showing in *U.S.* agriculture that wages of persons who have attended college are higher relative to others in states where the rate of productivity advance is most rapid. There are by now a number of available papers that report evidence of links between allocative efficiency and schooling in agriculture.[5] These studies include data for the United States, Brazil, Colombia, India, and Taiwan, and to me the cumulative impact is convincing. Unfortunately, except for the Carnoy paper, we do not have evidence of whether similar relations hold outside agriculture. For other industries, we remain largely ignorant of the role of education in production.

What of schooling as a screening device? The basic argument is that part of the role of schools is the identification of preexistent skills. If an individual's productivity does not depend upon the market's perception of his ability and his wage does, this possibility drives a wedge between private and social returns to schooling. The idea that an individual's product is independent of assessments of ability is puzzling. It seems reasonable that a person with high ability who is perceived as having low ability would be assigned tasks in which he would be less productive than he might otherwise be. Nonetheless, if both workers and employers are ignorant of individual ability and if schools serve an identification role, I find it hard to conceive of market experiments which distinguish this from a world in which schools produce rather than identify skills. Markets presumably reward skills independently of their origin.

The model spelled out by M. Spence is different. In it, workers initially know their abilities. Employers are ignorant and turn to schools for estimates of ability. K. Wolpin attempts to test this model by contrasting schooling levels and estimates of income returns to schooling between self-employed and private wage and salary workers. He finds, for the *NBER*-Thorndike sample, similar school completion distributions and similar estimates for the return to schooling for these groups. The novelty of this approach is that, in a world where the income return to schooling is derived exclusively from schooling's role in supplying information to employers, we are immediately suspicious of incentives for those who will be self-employed to go to school. It is not surprising that measured returns to school completion are equal for the two groups for more schooled workers are posited by the screening models as having more ability. Yet, one wonders why self-employed workers go to school at all if their productivity is not enhanced by the process.[6]

---

[5] The authors include: N. Khaldi, G. Fane, C. Wu, S. Sidhu, T. Haller, F. Patrick and E. Kehrberg, Welch (1970) and W. Huffman.

If I can make an overall criticism of research into income-schooling relationships, it is that it seems superficial. For too long we have proceeded as though there is something intrinsically meaningful about the number of years of school a person has completed. Except for the model of Ben-Porath and the solutions presented by W. Haley and Lillard, we do not have clear statements of the endogenicity of schooling vis-à-vis ability. Most importantly, we have not been able to generalize in regard to the role of family background as it contributes to motivation, to the "quality" of the learning environment, and to access to funds for investments in human capital. Similarly, I cannot point either to a single cogent discussion of the various dimensions of ability or to empirical evidence pertaining to determinants of differential values for different kinds of ability. We remain very ignorant about the impact of quality of schooling and of its various dimensions. We presume that somehow it matters what schools do. But what they are doing varies within schools and between schools at a point in time and through time.

It seems that a full description of individual differences in earnings capacity would answer these questions: (1) Within a market, what is the nature of the various human skills that affect earnings? (2) What determines variations in the level of remuneration for given skills between markets? (3) What factors determine the distributions of skills among individuals? Given our ignorance of these questions, I do not think we can be very sanguine about the accomplishments of labor economics in general and of human capital economics in particular. Human capital approaches have highlighted schooling and all that it conceals as "the" skill of interest. At the expense of this myopia in regard to the first question on the above list we remain largely ignorant of answers to the second and third.

III. Race Differences in Earnings

In the last two decades there has been a proliferation of economic theories of discrimination and of empirical studies which measure racial differences in earnings. Yet in this, more than any area I know of, the dialogue between theory and data has been minimized.[7] If there is blame, it seems to me that the major fault should be assigned to the theories, for they have failed in describing what the data show. I take four empirical "facts" as given. One fact is that, throughout the period for which data are available, black earnings in the United States have been less than white earnings. The second is that black-white differences in earnings have, at least in the recent past, been declining. The third is that black-white skill differentials are declining. And the fourth is that labor markets are increasingly integrated.[8] To this list, I would add that, historically, income returns to schooling have been less for blacks than for whites but recently, at least for those with "some college," returns to schooling are at least as high for blacks as for whites (Welch, 1973, or Smith and Welch).

---

[6] There are, of course, taste and insurance factors which would enter the schooling decision. But whatever the dimensions of the decision, schooling should be less attractive to those who get no directly marketable skills from it.

[7] I exempt the papers by W. Landes on fair employment legislation and R. Freeman on "public" discrimination from this criticism.

[8] Evidence of the first point seems unnecessary. However, there is some recent data (A. Horowitz) on females showing that during the 1960's earnings of black females surpassed earnings of white females. These data are highly aggregative and it is unclear whether the result will withstand decomposition by age, schooling, and work experience. For the second point, see the analysis of the *U.S.* Censuses in 1960 and 1970 by J. Smith and Welch, and the papers by Horowitz and W. Vroman. The third point can easily be verified if confidence is placed in schooling as a nominal skill index by any aggregated data source. Finally, the fourth point is largely a guess but is backed by evidence of convergent occupational and industrial employment patterns shown in the 1960's via census comparisons and in O. Ashenfelter's analysis of unions in the United States.

Now consider theories of discrimination. The original work of Becker and extensions by K. J. Arrow focus mainly on taste.[9] Both workers and employers are presumed to care about the race composition of the work force within firms. Consumers, on the other hand, are presumed indifferent about the race composition of labor employed in production of impersonal products. From this it follows immediately that employers who discriminate by paying higher wages to whites, whom they prefer, than is necessary in view of opportunities for hiring similarly qualified blacks do so at the expense of nominal profits. The long-term instability of such models is obvious. I know of no empirical attempt to verify that profits of firms depend upon the racial composition of their work force. Further, I think this omission itself is evidence that we fail to take seriously the most obvious implication of employer discrimination.

Discrimination by employees is more interesting. If employees require higher wages to work in integrated firms, then discriminatory equilibria are possible. They are not possible if all laborers are perfect technical substitutes, for in this case the theory degenerates into a prediction of completely segregated production. But if blacks and whites are not perfect substitutes, integrated equilibria can emerge in which the marginal cost of hiring a worker includes his wage and may also include the cost which the firm realizes in having to compensate other workers for whatever psychic losses they incur as a result of adding the worker under consideration. But what are the longer term implications of such equilibria?

Suppose that there are only two types of labor, skilled and unskilled, and suppose that production is a linear homogeneous function of these inputs. If the distribution of whites between skilled and unskilled labor is the same as for blacks, the resulting market equilibrium will be one of complete segregation without wage discrimination. If, on the other hand, a higher proportion of black labor is unskilled, partially integrated production may result. This is not a necessary consequence for, as Stiglitz notes, whites may specialize disproportionately in production of skill-intensive products and trade between products can substitute perfectly for integration.

But suppose there is only one product. In this case, neither skilled blacks nor unskilled whites would work in integrated firms. Some unskilled blacks and some skilled whites would be integrated to the extent that the complementarities of joint production compensate for diseconomics of association. The resultant equilibrium would entail higher wages for the relatively scarce, skilled black workers than for skilled white labor and lower wages for unskilled blacks than for unskilled whites. Over time the ratio of skilled to unskilled black labor rises relative to that of whites in response to the premium on black skill and, consequently, the extent of integrated production declines.

I suspect that the static predictions of this "theory" are historically satisfied in the United States. On balance, I suppose that whites have been disproportionately employed in skill-intensive industries. I also suppose that there has historically been more integrated production involving skilled whites and unskilled blacks than has involved integration of skilled blacks with unskilled whites. But it seems to me that the dynamic predictions vis-à-vis the extent of integration have been contradicted. Certainly the prediction of convergent skill distributions is satisfied, but has skill convergence resulted in increased segregation? I do not think so. Historically the bulk of black college graduates has entered professions that largely service black clientele. More recently black college graduates are entering managerial and engineering professions, and I am convinced that this change has been coincident with increased integration.

---

[9] In this section, I draw heavily from the excellent summary provided by J. E. Stiglitz.

Economic theories of discrimination, at least the taste-based theories, have tended to be theories of segregation rather than theories of wage differences, and their predictions of rising segregation through time are not supported empirically. On the other hand, empirical analyses of discrimination focus almost exclusively on wages. Race differences in wages are partitioned into direct and indirect components. Indirect effects refer to differentials associated with worker characteristics, such as schooling, and direct effects refer to race differences in parameters of estimated regression equations. This kind of partitioning is valuable since it offers information relevant to understanding origins of discrimination. But clearly the estimated direct effects do not fully "measure" discrimination: questions of underlying causes of differences in characteristics are also important.

For example, human-capital-styled theories focus both on the costs and returns to investments in skill. Discriminatory theories predict higher returns to skill acquisition for groups in which skill is most scarce, but empirical verification of the existence of these premia founder on the question of the quality of schooling. Although we remain largely ignorant about ingredients of school quality, speculations about the impact of race differences in quality of schooling abound. The reasons are obvious.

First, discrimination in publicly provided services is easier to understand since costs to discriminators are less apparent than is true of market discrimination. Second, insofar as school quality is concerned, there are implications both for costs and returns. If we ignore market discrimination and assume that private costs of schooling are described fully by the opportunity costs of a student's time, it is clear that returns as compared to the costs of schooling are higher where quality is higher, i.e., where the public subsidy is greatest. This comparison is flawed both by market discrimination and by the possibility of productivity differences that would exist independently of schools. But it is clear in any case that school quality is a legitimate concern, and the historical record of large race differences in attributes of schools is evident.

I, for one, do not think we have gained much insight of discriminatory mechanisms either from theories of discrimination or from measures of wage differentials. In the early discussion, public discrimination was dismissed. It was too obvious and did not tax our intellectual capital. I think we should reexamine this earlier omission. The historical experience with black schools in the United States offers a point of departure. Following disfranchisement in the last quarter of the nineteenth century, quality of black schools deteriorated reaching a nadir sometime in the early part of the twentieth century.[10] Then black schools began to compare increasingly favorably to white schools. This improvement was clearly under way in the 1930's and continued at least through 1960, without an apparently significant deviation from trend in 1954, the time of the desegration decision. If we could explain reasons for the decline following disfranchisement and the subsequent steady improvement that, significantly, led refranchisement, I think we would have at least begun to understand public discrimination.

---

[10] Here, by quality I mean any of measurable attributes of schools: expenditures per pupil, teacher salaries, retardation rates, days attended per year, teacher/pupil ratios, etc. See Welch (1974a).

Regarding market discrimination, there are a number of important unanswered questions. I am, however, not sanguine about prospects of data adequate for their resolution. One involves the vintage life-cycle nexus. Distinctions can only be made with observations through time, but then we must be able to reconcile these data with effects of market fluctuations. Another involves questions of effects of "statistical" discrimination. How closely is one tied to the mean performance of people "like" him? Of particular concern is the issue of self-fulfilling prophecies. Until we gain information about ties between true productivity and perceptions of productivity, we will remain ignorant about what may be a fundamentally important source of discrimination. Suppose an individual's actual productivity is bounded by perceptions of his ability: workers assigned to highly routinized tasks cannot demonstrate originality or imagination. In such a world returns to individuality to a person distinguishing himself from his peers may be slight in comparison to costs. And prophecies of group productivity differentials may become self-fulfilling.

IV. Concluding Comment

I have discussed only three of an array of topics that concern those who work with human capital theory. Life-cycle earnings patterns are the core of this theory while underlying sources of income returns to schooling and race differences in wages are not necessarily related to it. In fact, I know of no "human capital theory of discrimination." Theories of human capital and of discrimination tend to be associated because both are parts of a comprehensive view of earnings differentials and because work by Becker serves as a benchmark in each area. The most recent developments in human capital theory include the new home economics and work on the economics of human fertility. It is somewhat early for evaluation of this effort, but the subjects are important and the potential is high. In any case, their point of departure consists of recognizing the fundamental role played by the cost of human time in the allocation of time. And this, more than any other insight, may be the most valued contribution of human capital theory.

The Problem with Human Capital Theory—A Marxian Critique

By SAMUEL BOWLES AND HERBERT GINTIS*

Neoclassical economists have long treated labor as a commodity. They have integrated work and the worker into their analytical framework by assuming the labor-wage exchange identical to other exchanges. Because the capitalist system appears to strip the social process of work of its nonexchange characteristics, neoclassical theorists could long rest satisfied with a simple commodity interpretation of labor. And with steadily increasing levels of resources devoted to the preparation of labor, in the form of child rearing, education, health, and training, the shift toward treating the worker more precisely as a capital good seems, at least in hindsight, to have been virtually inevitable.

Human capital theory allows fundamental insights not available to earlier versions of neoclassical economics. First, it returns to and extends the Ricardian and Marxian tradition in treating labor as a produced means of production, whose characteristics depend on the total configuration of economic forces. Second, it rejects the simplistic assumption of homogeneous labor and centers attention on the differentiation of the labor force. Third, it brings basic social institutions (such as schooling and the family), previously relegated to the purely cultural and superstructural spheres, into the realm of economic analysis.

Yet this degree of success is secured at a considerable price: "labor" disappears as a fundamental explanatory category and is absorbed into a concept of capital in no way enriched to handle labor's special character. One gets the uneasy feeling that the operation was successful, but the patient vanished! The only specific attributes which "labor" retains in the human capital formulation derives from the fact, stressed by Alfred Marshall, that labor is embodied in human beings.

Human capital theory is the most recent, and perhaps ultimate, step in the elimination of class as a central economic concept. Beginning with the decline of Ricardian economics in England in the 1830's, non-Marxian economic theory has moved steadily away from attributing control of factors of production to identifiable groups and toward a theory of factor payments which self-consciously abstracts from the specific nature of the productive factors involved. In modern general equilibrium theory one can hardly tell the inputs from the outputs, much less distinguish among any specific inputs. Human capital theory is an expression of this tendency: every worker, the human capital theorists are fond of observing, is now a capitalist.

We find the theory to be substantially misleading both as a framework for empirical research and as a guide to policy. Our critique is not based on some of the commonly recognized shortcomings of the theory; for example, that market imperfections, monopoly and labor unions in particular, drive a wedge between marginal products and wages. Nor will we espouse the "training robbery" interpretation of schooling. While we recognize that educational credentials perform an important function, we are not ready to reduce the school system's economically relevant activities to screening and labeling; we believe that the evidence strongly supports the view that schooling enhances worker productivity. Nor will we dwell upon the problems which arise because skills are embodied in human beings: incomplete capital markets, imperfect information, and the possible divergence of interest between decision makers (parents) and recipients of the investment (children). Nor will we base our critique on the repugnance some have expressed at the notion of placing a dollar value on human beings. Our critique is, we believe, rather more fundamental.

By restricting its analysis to the interaction of exogenously given individual preferences, raw materials (individual abilities) and alternative production technologies, human capital theory formally excludes the relevance of class and class conflict to the explication of labor market phenomena. However, in our view such basic phenomena as the wage structure, the individual attributes valued on the labor market, and the social relations of the educational process itself can only be accounted for through an explicit class analysis. (A more detailed statement of this argument and the following material, with extensive documentation and references, is presented in our forthcoming book.)

Capitalism is a system in which the means of production are owned and controlled by a small minority. The mass of individuals, cut off from control of productive resources, are forced to sell their labor power to exist. Schooling, occupational training, child rearing, and health care perform dual economic functions: they play an essential, if indirect, role in production; and they are also essential to the perpetuation of the entire economic and social order. These processes can not be understood without reference to the social requirements for the reproduction from period to period of the capitalist class structure, the individuals who compose it, and the economic institutions that regulate it. Thus, an adequate theory of human resources must comprise both a theory of production and of social reproduction. The theory of human capital offers no theory of reproduction at all and presents a very partial theory of production, one which abstracts from the social relations of production in favor of technical relations. In the remaining sections we will argue that the failure to encompass social relations and to offer a theory of reproduction accounts for the more serious shortcomings of the standard treatments of the demand for human capital by firms, the supply of human capital, and the interpretation of the theory's central analytical concept: the rate of return to human capital.

I. The Demand for Human Capital by Firms

Our critique of human capital theory stems from a Marxian theory of the capitalist firm, one which is quite at odds with the usual neoclassical treatment.

First, we view production as a social as well as technical process. We reject the neoclassical notion of the firm as a black box whose inner workings are of interest, perhaps to the organization theorist, but not to the economist. The firm has sociopolitical dimensions which the economist may abstract from only at the cost of significant error.

Second, production is always joint production, constituting a transformation of raw materials into products and of workers with given skills and types of consciousness into workers with altered (or stabilized) skills and consciousness.

Third, labor is not a commodity, but rather an active agent whose efforts on behalf of its own objectives must be channeled, thwarted, or used to generate profits.

Fourth, the structure of wage rates is not exogenous to the firm, but rather one of the instruments used to maximize profits.

In this framework, to treat the labor-wage exchange as a pure market exchange is to abstract from an essential element in the capitalist organization: the power of the capitalist over the worker. Pure exchange relations involve no explicit power relations because the coercive instruments guaranteeing the integrity of the exchange "contract" lie outside the jurisdiction of the exchanging parties. In commodity exchange "What you see is what you get," and failing this, the aggrieved party has significant legal recourse. Not so in the case of the labor exchange which is marked by the absence of a real *quid pro quo.*

We may formalize this argument by introducing Marx's distinction between "labor" and "labor power." Labor power is the capacity of the individual to contribute to the production process in its current technical and organizational form. Thus labor power is a commodity, defined by the worker's physical and mental capacities and skills, behavioral characteristics, and potential impact on the performance of others involved in cooperative production. The labor power of the individual specifies the maximum level of performance evincible from him or her by the capitalist, given current technical and organizational conditions. The market aspect of the relation of worker to capitalist is as follows: the prospective employee agrees to surrender disposition over his or her labor power to the capitalist in return for a wage. The "labor" or actual work supplied by the individual, by contrast, is not determined in the sphere of exchange relations at all. Labor, which represents the concrete activity engaged in during the production process, depends in an essential way on the social and political structure of the enterprise.

Peak-level performance by workers benefits the capitalist rather than the worker. Actual labor productivity will normally fall short of the maximum possible with the available labor power. However, the value of the (average) product of labor will normally exceed the value of labor power (the wage), giving rise to profits. Profits on a given stock of money capital are thus maximized by exploiting the labor power of each worker to the fullest, that is, by getting as much labor as possible out of each worker. Profits are also enhanced by holding down the value of labor power, the wage. Both objectives are pursued through a judicious choice of workers and a proper specification of the technical, organizational, and political structure of the enterprise. The social organization of production is in large measure a reflection of the capitalists' need for incentive and control mechanisms which will extract labor from workers at the lowest possible wage and prevent the formation of worker coalitions which could oppose their power.

The class nature of the production process follows immediately upon observing that incentive and control mechanisms and the types of potential workers coalitions are dependent on the ownership and control structures of the enterprise. The worker attributes, which are valued by employers and which therefore constitute "human capital," are not limited to technical skills and abstract productive capacities. In particular, such ascriptive attributes as race, sex, age, ethnicity, and formal credentials, often held to be irrelevant in the logic of capitalist production, are used to fragment the work force and reduce the potential formation of coalitions within the firm. "Modes of self-presentation," to use Erving Goffman's term, such as manner of dress, speech, personal demeanor and life-style, self-concept, and status identity, can serve the same ends, while in addition insuring a relatively undistorted transmission of directives down and information up the ladder of hierarchical authority of the enterprise. Moreover, as Richard C. Edwards has shown, such work-relevant personality traits as resignation to or approval of the structure of control and distribution of rewards in the enterprise, dependability and orientation to authority within this structure, and propensity to respond individualistically to incentive mechanisms are directly relevant to extracting work from workers.

The allocation of workers to job slots, the structure of jobs available, and the definition of "productive" worker attributes simply cannot be derived, as the human capital theorists would have it, from a market-mediated matching of technically defined skills with technically defined production requirements. Issues of power, and ultimately of class, enter on a rather fundamental level.

II. The Supply of Human Capital

According to human capital theory, individuals exhibiting a particular subjective rate of time preference, and faced with an array of jobs having specified pecuniary and nonpecuniary attractions and requiring certain skills, will embark upon a course of investment in personal development. The supply of human capital is the simple aggregation of these individual choices. The demand for those services which turn raw potentials into developed capacities is derived from the individual demand for human capital. These services, "education" for short, account for the treatment of labor as a "produced means of production." In this view, the history and current state of education is the product of individual choice constrained, of course, by available educational and production technologies and the total supply of resources. Likewise, an individual's pattern of personal development (in short, how one "turns out") is depicted as the product of one's own or one's family's choices, limited only by one's "abilities," by the available learning technologies, and to a limited extent by one's family resources.

An examination of the dynamics of personal development and of the *U.S.* educational system presents a substantially different and far more complex picture. No doubt education is in part organized to produce worker traits demanded by employers. Indeed we have elsewhere sought to document the proposition that schools produce "better" workers primarily through the structural correspondence of the social relations of education with those of capitalist production, rather than through the content of the academic curriculum. Yet the social organization of schooling can in no way be depicted as the result of an aggregation of individual choices. The history of educational innovation indicates clearly that the social relations of education were rarely a reflection of popular demands, expressed either through the market or the political process. Recent research by Michael Katz, David Tyack, and others reveals that changes in classroom techniques, school finance and control, and other aspects of the organization of schools were more often than not introduced by professional elites against popular resistance.

Moreover, the production of "better workers" cannot be understood simply by reference to how individual worker-skills are related to individual worker-productivities. A highly skilled work force is not necessarily a profitable work force. Thus the educational system does much more than produce human capital. It segments the work force, forestalls the development of working class consciousness, and legitimates economic inequality by providing an open, objective, and ostensibly meritocratic mechanism for assigning individuals to unequal occupational positions. For example, the use of *IQ* and cognitive performance measures is essential to the legitimating function of schooling. Yet the use of these tests as screening devices in education goes far beyond their objective relevance to job adequacy and probably inhibits the most rational allocation of human resources. This fact is hardly compatible with the individual choice-aggregation approach and suggests that more basic social forces may be at work.

We believe these social forces derive from a basic contradiction in capitalist development: the accumulation of capital, central to the expanded reproduction of the economic system, at the same time undermines the process of reproduction of the capitalist order through the creation of a large, potentially class-conscious body of wage-workers and through dramatic shifts in the class structure. The structure of *U.S.* education, we have argued elsewhere, evolved historically in response to struggles arising from this basic contradiction. Many of these struggles have operated, in true pluralistic fashion, through the relatively uncoordinated "investment" decisions of individuals and groups as mediated by local school boards, the market for private educational services, and other decentralized decision-making arenas.

Yet the accommodation of the educational system to a changing economic reality, however pluralistic, is in essence a process led by the changing structure of production. And the evolution of the structure of production is governed by the pursuit of profit and privilege by those elements of the capitalist class which dominate the dynamic sectors of the economy. The process of individual choice aggregation, even when it is relevant to educational change, works within economic constraints determined almost entirely outside both the consumer's and the citizen's arena of choice.

Moreover, during critical periods in which basic institutional changes have been undertaken, 1840–60 or 1890–1920, for example, the individual choice model appears to be of dubious relevance to the changing structure and extent of schooling. Rather, an explicit class analysis seems best to explain the process of change and accommodation.

We are led to reject the individual choice model as the basis for a theory of the supply of educational services. The model is not wrong—individuals and families do make choices, and may even make educational choices roughly as described by the human capital theorists. We reject the individual choice framework because it is so superficial as to be virtually irrelevant to the task of understanding why we have the kind of schools and the amount of schooling that we do. It is no more able to shed light on why we "turn out" the way we do. The history of *U.S.* education or the process of individual development could probably be described in terms of functions measuring the returns to human capital and cost of capital. But what would be gained by this? The human capital approach, because it rigidly eschews class concepts, cannot offer a compelling explanation of the location of these functions or why they shift as they do, and thus cannot provide a useful theory of the supply of educational services.

We would like to offer two additional criticisms. First, economically relevant skills are not unidimensional; they cannot be aggregated into a single measure of which some individuals will have more and others less. Even in a purely formal sense, the reduction of heterogenous labor to a single "human capital" measure presents serious problems in a general equilibrium framework. Quite apart from formal problems, it is virtually impossible to make sense of the economics of human development in the United States using a model which fails to recognize that families and schools teach different things to different people—not simply more or less. The graded and cumulative academic curriculum gives the appearance of a definite hierarchy of achievement. But even in the cognitive realm we suspect that different types of learning are readily identifiable; rote-learning for some, problem-solving for others, for example. And in the noncognitive aspects of learning—the so-called hidden curriculum—different dimensions of learning are consciously either offered or imposed on children. E. B. Leacock, Jeanne Binstock, and others have shown that these differing learning contexts are closely associated with the racial, sexual, and class characteristics of the student body. Similarly, Melvin Kohn has demonstrated among families a dramatic correspondence between the objectives of child rearing and the social relations of production which confront the primary wage earner in the family.

Our second point relates to the schizophrenic usage of the word capital. The justification for the expression "human capital" is the fact that skills, like other assets, constitute a claim on future income. This usage is thoroughly in the neoclassical tradition. In the earlier, classical tradition the concept capital encompassed and unified two distinct aspects: the claim on future income and the ownership and control over the means of production. Except to the very limited extent that learning allows one to go into production on one's own, education cannot be called capital in the classical sense. Unless one accepts John Kenneth Galbraith's view of the hegemony of the technostructure (an unlikely orientation for the human capital school!), it must be admitted that educated workers do not control, much less own, the means of production. Yet it is precisely this latter, classical sense of the word capital which provides the ideological impact to the statement that every worker is now a capitalist.

III. The Returns to Schooling

Why is there a positive net return to human resource investment? What explains the pattern of rates of return? The human capital analyst, equipped with nothing more than a black box theory of both the firm and the school, is forced to offer explanations which are either superficial (supply and demand) or misleading (the interaction of tastes, technologies, and abilities). To the extent that any more specific explanations are suggested—for example, that schooling increases worker productivity through increasing individuals' cognitive capacities, and that learning abilities differ—the theory, as we have demonstrated elsewhere, is substantially incorrect. Nor are these questions unimportant. Indeed, the interpretation of the rate of return to human capital hinges upon the answer.

Our alternative theory of human resources, sketched briefly in the previous two sections, suggests the following answer to the first question, addressed specifically to the case of schooling. In the class model of the firm sketched above, the wage may under some conditions reflect marginal revenue product. But schooling will raise marginal revenue products in a variety of ways. First, investment in education may increase the labor power of the individual, either through increasing skills and productive capacities, or through supplying credentials which enhance supervisory authority. Second, schooling may increase the ease with which the employer can extract labor from a worker with given labor power by generating or selecting individual motivational patterns more compatible with the class-based power structure and incentive mechanisms of the enterprise. Third, the educated worker may be more valuable through his or her overall impact on the size of the wage bill, in that the segmentation of workers by income and status characteristics inhibits the formation of coalitions of workers capable of countering the power of the capitalist.

We may add that, because of the essential role of education in reproducing the capitalist order as a whole, the capitalist class has an interest in schooling which transcends any narrow calculation of marginal revenue products at the enterprise level. Because the capitalist class pursues its long-run interests through the state, and in important measure through its influence on educational policy, the structure of rates of return to education will reflect the often contradictory requirements of capitalist production and the reproduction of the class structure. It follows immediately that there is no reason at all to expect equality in rates of return, either among different types of schooling or between schooling and other forms of investment.

Even confining attention to the individual capitalist enterprise and thereby abstracting from class collusion by capitalists, our interpretation suggests a structure of rates of return which roughly corresponds to the observed pattern. The economic return to schooling and to age is in large part a return to a characteristic which allows the legitimate and effective exercise of authority over other workers. Black and female workers, who are by and large excluded from exercising authority over any but workers of their own sex and race, are likely for this reason to earn lower returns to schooling. Moreover, less well educated workers are, for the same reason, unlikely to gain a high return to aging; and analogously, younger workers even if white and male generally must await the arrival of a few gray hairs before enjoying any substantial return to schooling. This interpretation based on the need of the capitalist to legitimate and reproduce the power structure of the firm provides, we believe, a far more compelling explanation of the actual pattern of rates of return than does the human capital theory. The distinctly *ad hoc* and not particularly compelling attempts by human capital theorists to explain the observed pattern of rates of return is to our minds symptomatic of the limitation of the entire approach.

IV. Implications and Conclusions

Our critique of human capital theory completed, if in abbreviated form, it remains only to draw out some of the implications. We will concentrate on three major areas of application of the theory: growth accounting, distribution, and public policy.

The human capital approach to economic growth exhibits the weaknesses of the theory in a particularly straightforward manner: all factors may "contribute to growth," and barring certain technical problems, these contributions can be numerically ascertained and summed. The task of human capital researchers is thus to determine the precise contribution of investment in human resources. Even were such imputation and aggregation abstractly possible (which the now well-developed Cambridge capital critique would maintain is not), it leaves the basic questions unstated, much less answered. For we must ask not only how variations in the level of investment affect the level of output and growth rates, but also how the structure of human capital formation affects the social relations of production and the evolution of class relations. In our formulation, schooling may influence the rate of growth positively or negatively in ways which go considerably beyond the human capital theorist's notion of "labor quality": through its role in the extension and reproduction of the wage-labor system, through its capacity to attenuate class conflict and thereby to alter the rate of capital accumulation, and so on. Indeed, given that a more productive and less irrational alternative to capitalism exists, and given the role of education in reproducing the capitalist order, the contribution of schooling to growth over the last half century may on balance have been negative.

A similar narrowness is exhibited in the human capital approach to the distribution of income. Family income is the sum of returns to the various factors "owned" by the family. Thus, a measure of inequality in family income can be decomposed into dispersions in the returns to the ownership of factors and their covariances. The contribution of changes in factor endowments, say through educational equalization, to changes in the distribution of income can then be calculated. The methodological weaknesses of this approach are considerable.

First, in the human capital formulation the distribution of income is determined solely by conditions of labor supply; demand conditions are considered in a highly abstract and unenlightening manner. Macroeconomic considerations, market structure, technical change, economic dualism, and other presumably central aspects of the distribution problem are ignored. More serious, perhaps, is the naive assumption that descriptive regularities possess explanatory power. It is likely that basic regularities in the distribution of income are not directly related to human resource differences but are structural characteristics of the capitalist economy, affected by the relative power of various classes, races, sexes, and other groups. Human resource differences facilitate the assignments of individuals to places in an array of economic positions whose income structure is determined in large measure independently of the distribution of human resources.

The relationship between schooling and the distribution of income cannot be understood with a model which lacks a theory of reproduction, for a central aspect of this relationship is the role played by the school system in legitimating economic inequality. Thus, it is illogical to suppose that the reduction in inequalities in the distribution of schooling might lead to changes in income inequality in any particular direction. Major changes in the distribution of human resources will predictably be associated with changes in the structural relationships (earnings functions) relating schooling to individual income. Indeed, an equalization of education might radically reduce economic inequality, not directly, but rather by undermining the legitimacy of inequality and thus enhancing the potential for a thoroughgoing reorganization of economic institutions based on conscious class struggles or other political conflicts.

Finally, the contribution of human capital theory, through public expenditure analysis, to a balanced social policy is minimal if not actually perverse. The human capital approach, particularly when applied to schooling, embraces one of the many well-known shortcomings of public expenditure analysis: the assumption of exogenously determined individual preferences is essential to neoclassical cost/benefit analysis, yet the educational system is a prime example of an institution geared toward the alteration of preferences themselves. Given that economic returns to education are functionally related to its impact on other welfare-relevant aspects of the individual (personality, consciousness, self-concept, and interpersonal behavior), the traditional defense of cost/benefit analysis—the rigid separation of "economic" and "non-economic" welfare—bears little logical cogency.

Again, the error in the human capital approach lies in its partial view of production and its abstraction from social reproduction. For example, the repressive nature of schooling, hardly a contribution to human welfare, is an integral part of the production of a disciplined work force and is directly related to the social relations of production. Likewise, the perpetuation of sexism, racism, and elitism in our schools would not be said to be welfare-conducive or even welfare-neutral by most human capital theorists. Yet these aspects of schooling play an essential role in the reproduction of the capitalist order, a role inseparable from the capacity of schools to produce "good" workers. By abstracting from the social relations of production and the role of schooling in the reproduction of capitalism, human capital theorists have put forth a one-dimensional normative framework for the analysis of educational decisions which has no reasonable relationship to human welfare.

The theory of human capital, like the rest of neoclassical economics, ultimately locates the sources of human happiness and misery in an interaction of human nature (preferences and "abilities") with nature itself (technologies and resources). This framework provides an elegant apology for almost any pattern of oppression or inequality (under capitalism, state socialism, or whatever), for it ultimately attributes social or personal ills either to the shortcomings of individuals or the unavoidable technical requisites of production. It provides, in short, a good ideology for the defense of the status quo. But it is a poor science for understanding either the workings of the capitalist economy or the way towards an economic order more conducive to human happiness.

SUPPLY AND MOBILITY OF WOMEN ECONOMISTS

Job Search and Affirmative Action

By ALICE H. AMSDEN AND COLLETTE MOSER*

In the first part of this paper, the recruitment and hiring practices in the job market for men and women economists in 1973–74 are examined with particular emphasis on the relationship between interviews and follow-up job offers. In the second part, the perceived effect of affirmative action implementation on employment and employment conditions over the past three years is reported.

I. Job Search in an Affirmative Action Context[1]

The 1973–74 job market for economists operated under the pressures of affirmative action (*AA*) which had been building up for a number of years. Several hypotheses about the possible effects of *AA* on the 1973–74 job market for economists were articulated by observers when recruitment and hiring were done. First, some observers suggested that, as designed and enforced, *AA* was window dressing. It was ineffective as a means to end what was assumed to be sex discrimination in employment. It also had the undesirable side effect of raising women's job search costs. Job search costs rose because prospective employers enthusiastically interviewed women without any intention of hiring them. This gave the appearance of complying with *AA* requirements. Second, some observers suggested that *AA* forced prospective employers not practicing discrimination zealously to recruit and hire women in order to be above suspicion. As a consequence of excessive interviewing, job recruitment costs rose. As a consequence of the total demand for top-rate women economists outstripping the supply, the quality of faculty declined. Third, some observers suggested that *AA* discriminated against men. Male economists had fewer opportunities than women to be interviewed and had fewer follow-up job offers.

Preliminary data from The Committee on the Status of Women in the Economics Profession (*CSWEP*), American Economic Association (*AEA*) 1974–75 Survey of Economists provide some insights into the recruitment and hiring practices of men and women economists in 1973–74. The extent to which *AA* influences such practices is as yet indeterminate and awaits time series analysis with precise quantitative measures of *AA*. This paper summarizes the information provided by those economists surveyed who participated in the 1973–74 job market.[2] It concentrates

[2] Information on the sampling and survey procedure and quality of sample may be obtained from *CSWEP, AEA*. Preliminary data from the 1974–75 *CSWEP, AEA* Survey of Economists used in this article are based on the 710 questionnaires returned by 55 percent of the women economists registered with *CSWEP, AEA*; the first 264 male economists in matched cohorts; and a special male job-market sample. The education cohort was selected at random from three names supplied by each woman economist of men who were in her class when the woman did her highest level of academic work. A name for the employment cohort was supplied by each woman, using an alphabetic criterion, of the male economist at her institution who holds the same rank or approximate level of job responsibility. The male job-market sample consists of two types of men thought to have been in the 1973–74 job market: (1) men whose names were supplied by women answering questionnaires (approximately 62 percent of the male job-market sample), and (2) men whose names were selected for sampling from the files of vitas received by

on the relationship between interviews and follow-up job offers of respondents. This is to shed light on the speculations which the 1973–74 job market generated. If it is found that the ratio of interviews to follow-up job offers differs between men and women when quality is controlled for, then the hypothesis that sex discrimination exists cannot be ruled out.

A distinction is drawn between three job markets. One concerns recruitment at the *AEA* meetings in New York City in December 1973, job offers directly resulting from initial interviews at the meetings, follow-up "intensive" interviews resulting from initial interviews at the meetings, and subsequent hiring. Another market concerns intensive interviews and follow-up job offers not arranged at the meetings. A third market concerns interviews and follow-up job offers unsolicited by candidates and arranged at the initiative of employers. The ratio, R, chosen to measure the relationship between initial interviews, I, and follow-up interviews or job offers, F, is the following:

$$R = (I - F)/I \tag{1}$$

The ratio can take a value of between zero and one. A high ratio indicates a poor follow-up record. Hence, R can be thought of as a measure of "excess interviewing." A value of zero indicates a perfect follow-up record.

The mean ratios calculated for job market respondents are presented in Table 1. They are broken down by state universities and colleges, private universities and colleges, government and business. Aggregate mean ratios for all four categories are also presented.

The comparative magnitudes of the five ratios for both sexes for the aggregated four categories of employers are consistent with a priori reasoning. R_1, the ratio of *AEA* initial interviews to direct follow-up job offers, is high for the aggregated four categories. As one would expect, not many employers make job offers solely on the basis of interviews at the meetings. R_5, the ratio of unsolicited job interviews to job offers, is low. Presumably interviews arranged specifically at the behest of employers are more likely to result in hiring than are all classes of interviews. It is noteworthy that, both for men and women, recruitment not initiated at the meetings, R_4, is more likely to result in hiring than recruitment initiated at the meetings.

What also emerges from Table 1 is the fairly small difference in the ratios of men and women for the aggregated four categories of employers. R_1, R_4, and R_5 are almost identical for both sexes. In the *AEA* job market, however, women tend to have a slightly better chance for a follow-up intensive interview, R_2, than do men. Men tend to have a slightly better chance for a follow-up job offer, R_3, than women. But in neither of these cases are the means for men and women significantly different from each other at the 96 percent level of confidence. The evidence suggests that, even in the year when affirmative action gained unprecedented publicity, the interview/follow-up record of women economists was no better than that of men.

When the ratios for men and women are disaggregated according to category of employer, three out of five of the ratios for private universities and colleges indicate a better follow-up record for men. Four out of five of the ratios for business indicate a better follow-up record for women. The samples from which most of the disaggre-

---

several economics department chairmen. These files were sent to the chairmen by placement officers throughout the country. Both parts of the job-market sample were relatively small (despite a fairly high response rate) and were nonrandom.

This article is based on the 262 women and 154 men who were in the job market; i.e., they had one or more job interviews or offers after October 1, 1973.

[a] $R_1=(m-n)/m$ where m = number of interviews at 1973 *AEA* meetings and n = number of job offers resulting from 'm'.

[b] $R_2=(m-o)/m$ where o = number of follow-up intensive interviews resulting from 'm'. By an intensive interview is meant a visit to a college, etc., for the purpose of meeting staff, presenting a paper and/or discussing employment.

[c] $R_3=(o-p)/o$ where p = number of job offers resulting from 'o'.

[d] $R_4=(q-r)/q$ where q = number of intensive interviews without prior *AEA* interview and r = number of job offers as a result of 'q'.

[e] $R_5=(s-t)/s$ where s = number of unsolicited intensive interviews and t = number of job offers resulting from 's'

gated ratios are calculated, however, are very small. Henceforth, the ratios presented will be limited to the aggregated four categories of employers.

An attempt was made to compare the interview/job-offer ratios for men and women drawn from a homogeneous sample. To control for quality, male and female respondents have been grouped according to the institution in which they undertook their Ph.D. training. This criterion for controlling quality, however, is far from perfect. It assumes a homogeneity of quality within each group that may not be warranted. The abilities of men and women with Ph.D.s from the top seven schools in economics, for example, may differ. This may be a consequence of the imposition of more stringent entrance requirements for women than for men because of a sex bias in graduate admissions policies. This would imply a higher quality of women graduates. Such a limitation must be kept in mind when interpreting the interview/follow-up ratios for men and women controlled by Ph.D. institutions. These ratios are presented in Table 2.

The evidence in Table 2 suggests that women graduates of the top seven schools in economics have a better follow-up record than men graduates of the same schools in three out of four cases. But the differences in mean ratios are not significant at the 96 percent level of confidence. The ratios for men and women graduates of other schools in the "Chairman's Group"

[a] See footnotes to Table 1 for definition.

are very similar. Male graduates of colleges and universities which are generally ranked lower academically than colleges and universities in the Chairman's Group have a better follow-up record than comparable female graduates. This may be some indication that employers have not succumbed to the pressures of *AA* by "overhiring" women with less than impeccable credentials compared to men of the same calibre. Firmer indication that academic standards have been maintained, however, would require comparing the academic rank of the institutions hiring such men with that of the institutions hiring such women.

Although men and women economists have similar interview/follow-up ratios, their opportunities for employment may differ. One indication that unequal opportunities for employment exist would be differences in absolute number of interviews for men and women. Table 3 presents the average number of initial *AEA* interviews, non-*AEA* interviews, and unsolicited interviews of male and female respondents. Such averages have also been broken down by the institution where Ph.D. work was undertaken. For each indicator of job opportunity (for example, non-*AEA* interviews), only respondents with at least one interview were sampled. This was to insure that the sample contained only respondents who were actively seeking employment. Not unexpectedly, both men and women had more *AEA* interviews on average than other types of interviews. Presumably the marginal cost of an additional interview at the meetings is less for both interviewer and interviewee than in other situations. There appears to be little indication that one sex had greater opportunities for employment than the other. This is true both when quality is controlled for and when it is not. The average number of interviews for men and women is quite similar. The possibility remains, however, that one sex found it easier than another to arrange even one interview. There may be more men than women who would have liked to be interviewed but were not.

An attempt was made to get some idea of the salaries offered to men and women job-searchers. Respondents were asked to specify both the salary of their first job offer and the salary of the job they accepted. They were also asked to break down these figures by state and private universities and colleges, government, and business. To make meaningful comparisons of male and female salary offers, however, it is necessary to control for two factors:

TABLE 3—AVERAGE NUMBER OF INTERVIEWS OF JOB-MARKET RESPONDENTS, OCT. 1973–NOV. 1974[a]

Item	Initial Interviews At The *AEA* Meetings		Non-*AEA* Interviews		Unsolicited Interviews

[a] Not every respondent provided information on the school from which Ph.D. was received. Therefore, the total number of respondents for "All universities and colleges" may in each category of interview exceed the subschool total.

the quality and experience of the job applicant and the character of the hiring institution. Salaries for the same position may vary by geographic region, for example. They may also vary by type of academic institution. It appears that, when academic institutions are ranked by quality along a spectrum, salaries for assistant professors approximate a normal curve. The highest and lowest ranking institutions pay the least. Differences such as these could not be controlled for on the basis of the questions respondents were asked. If, however, it is assumed that differences in institutions hiring women and in institutions hiring men are distributed randomly, the figures presented in Table 4 give a very rough indication of the comparable magnitude of the salaries offered to men and women. Only the salaries of jobs accepted are presented for all job respondents, irrespective of position. The profile of positions of male and female respondents who provided information on salaries, however, appears to be fairly similar. The figures indicate no consistent pattern of differences between the sexes. This was also the case when candidates were grouped according to institution where they undertook their Ph.D. work. Nor was there a consistent

pattern of differences in the salaries of first job offers made to men and women.

The sample results may be summarized as follows: first, the hypothesis that the job-search costs of women in 1973–74 were higher than those of men because employers interviewed women without any intention of hiring them is not supported by the data. On the other hand, even in the presence of an intensification of *AA*, the interview/follow-up record of women economists was no better than that of men. Second, there is some indication that the quality of faculty did not decline in the presence of *AA*. Women Ph.D. graduates of relatively less prestigious schools did not have a better follow-up record than men graduates of the same academic institutions. Third, it does not appear that one sex had more opportunities for employment than the other. The average number of interviews for men and women with at least one interview is fairly similar. Fourth, the salaries offered to men and women show no consistent pattern of differences.

There is room for much more work to better explain variations in the five interview/follow-up ratios. Additional coding of the sample data would permit regressions to be run for each of the five dependent ratios. One set of explanatory variables might include marital status, children, and mobility of spouse. Such variables are believed to influence the decision to hire women in particular. Another set of independent variables to explain the relationship between recruitment and hiring might include institution where Ph.D. work was undertaken, prime field of specialization, academic position, helpfulness and prominence of thesis adviser, and number of publications. Sample data on all these variables have been collected. This type of analysis, however, is only one of the many directions which further research might take.

II. Perceptions of Affirmative Action Issues[3]

The late 1960's and early 1970's witnessed the implementation of several pieces of legislation relating to the employment of women. Notable among these are the Equal Pay Act which requires that men and women doing substantially the same work receive equal pay; Title VII of the Civil Rights Act which mandates the removal of various discriminatory employment activities; amendments to the Higher Education Act and Executive Order 11246 and Revised Orders 4 and 14 requiring that employers with government contracts develop affirmative action plans for improving women's employment opportunities and equity.

Affirmative action policies relate to the education and employment of women economists as well as women in other occupations. Some areas for affirmative action are as follows: recruitment and interviewing; the numbers of women hired in previous "male only" jobs; job assignments and responsibilities; wages, fringe benefits, and other methods of remuneration; promotion and upward mobility; treatment with respect to layoffs, discharges, and hours of work.

Implementation of affirmative action policies involves both direct changes in the variables cited in the previous paragraph and indirect personal interaction changes which might affect one's perception of the "acceptance" of a woman in an occupation. Such acceptance is expected to generate an increase in the supply of women in that field.

Given these affirmative action principles and policies, the Committee on the Status of Women in the Economics Profession included in its survey a set of questions with the following major purposes:

---

[3] Part II was written by Moser.

(1) to evaluate economists' perceptions of changes in areas of employment related to affirmative action implementation, and

(2) to evaluate economists' perceptions of the continuation of differential treatment based on sex even within this affirmative action implementation period.

The affirmative action question set, Part IV of the survey, included seven separate questions. One of these questions was a "grid" of ten areas of employment or employment conditions in which one might expect some perceived change as a result of affirmative action implementation. The phrase "during the last three years" was used as a proxy for the implementation period. Sample size was 710 women and 332 men. The response rate for most of the affirmative action questions was 95–98 percent of this sample. On the ten-question "grid," the response rate fell to an average of about 65 percent for women and 55 percent for men.

The majority of the respondents were situated in establishments which had affirmative action plans for women. Fifty-seven to 60 percent of all men and women respondents said that their establishment had either a written or verbal plan. Only 4 percent of the women and 7 percent of the men said that their establishment *did not* have such a plan.

Answers to the ten-question grid concerning areas of employment conditions within the last three years are particularly relevant given this degree of awareness of existence of institutional affirmative action plans. Respondents were asked whether they had observed certain employment changes with respect to themselves (if they were women), and with respect to other women economists; whether no change had been observed; whether the issue really was not "a problem"; or whether opportunities for women economists had actually worsened in this area. Since responses to the last outcome (opportunities worsened) were minimal, they were dropped from the reported tabulations. Responses to the first two outcomes were combined to form a category which indicated improvements for women.

Six of the affirmative action employment-related issues lent themselves to the above kinds of treatment. These areas are as follows: (1) increased access to tenure, seniority, or promotion for women; (2) affirmative action salary adjustments for women economists; (3) increased administrative responsibilities for women, including increased appointments to important committees; (4) increased support of women economists by male colleagues; (5) increased support of women economists by students and other clients; (6) increases in fringe benefits and such perquisites as financial support for conference attendance.

The most frequent observation on each of these questions related to improvements in employment conditions for women economists was that no change had occurred. Only in the area of increased administrative responsibility and committee assignments did the number of women respondents indicating change almost equal the number observing no change. Women saw the least amount of change in the area of fringe benefits.

Another consistent outcome for each of these employment issues was that one and a half to twice the percentage of men to the percentage of women *did not* see the issue as a problem for women economists in their department or division. Table 5 summarizes these results.

In an effort to determine the extent of perceived employment discrimination by sex during this three-year period of affir-

TABLE 5—PERCEPTIONS OF AFFIRMATIVE ACTION AREAS OF EMPLOYMENT FOR WOMEN ECONOMISTS

Observations	Issues

Men: "not a problem"	35.0	34.9	33.9	34.1	35.1	41.1

Source: Preliminary data from *CSWEP*, *AEA* 1974–75 Survey of Economists.

mative action implementation, respondents were asked a few other questions related to employment conditions, employer preferences, and interviewing tactics.

A key question was whether respondents working as economists thought that they were paid less or had a lower job level than what they would have if they were of the opposite sex. Of the women respondents, 34.7 percent believed this to be the case. A much smaller percent of the men, 13, believed they were paid less or had a lower position because they were men. In the open-ended part of this question which asked "yes" respondents to indicate how this "gap" occurred, a sample of male respondents overwhelmingly asserted affirmative action to be the cause. Women respondents gave much more mixed interpretations. Of a sample of about 300 female respondents, the most frequent explanation given was that the gap occurred at hiring, oftentimes because the woman was not an aggressive bargainer or through her lack of comparative salary data.

Very frequently women economists cited restrictions on promotion and limited access to administrative positions as the cause of the earnings and position gap. Attribution of the gap to discontinuous labor force association, a factor emphasized by G. E. Johnson and F. P. Stafford was given by only four of the women respondents in the sample.

Respondents were also asked whether in the last three years an employer had indicated in their presence a preference for male rather than female economists. About 23 percent of the women and 9 percent of the men indicated that this situation had occurred. The magnitude of the positive response to this question is surprising in this affirmative action period. Also inconsistent with affirmative action principles were the "reasons" which respondents said employers gave for their preferences. While "children and family responsibilities" were cited by several respondents, subjective perceptions of female characteristics, such as "unstable," "not serious," "not smart," "can't get along with coworkers," were given to a larger number of female and male respondents as the employer's explanation for preferring male to female economists.

While the previous question did not necessarily refer to employer preferences for men expressed at the time of an interview, a question was asked on an interviewing procedure wherein the employer's questioning concentrates on nonprofessional competency issues. Of the women who had taken interviews in the last three years, 160 or 31.9 percent reported that they had received interviews in which a disproportionate amount of questioning was related to personal and domestic issues. Only 11 men (4.3 percent of the males taking interviews) reported that they had been subjected to this kind of interviewing.

The early 1970's witnessed large-scale attempts to implement affirmative action employment concepts. Responses to the *CSWEP* survey affirmative action questions indicate that about one-fourth to one-third of our respondents are observing improvements for women economists in terms of their conditions of employment. Analysis of other questions related to perceived acts of employment discrimination against women indicates that a significant portion, perhaps one-third, of our women respondents feel that they have been subjected to this kind of discriminatory treatment even during this assumed period of affirmative action implementation. The strength of the no-change responses, as well as the indications of continued differential and unfavorable treatment of women economists, does not suggest a reversal of attitudes. Even with affirmative action programs, improvements for women economists seem to be marginal.

Women Economists: Career Aspirations, Education, and Training

By MYRA H. STROBER*

The economics profession is, at the present time, predominantly male. According to the 1970 census, women are only 12 percent of all economists and only 14 percent of economists teaching at colleges and universities. Moreover, among those currently training to become economists, the percentage of women is also quite low. In a 1973 study of the fifty-seven major American economics departments (see Carolyn Bell, 1974) the American Economic Association (*AEA*) Committee on The Status of Women in the Economics Profession (*CSWEP*) found that women are only 12 percent of current full-time Ph.D. candidates, 14 percent of full-time M.A. candidates, and 15 percent of senior economics majors.

Occupational segregation, such as that existing in the economics profession, is beginning to be recognized as a serious misallocation of resources; and efforts to reduce such segregation are now being made in many places. At its December 1971 meeting, the *AEA* resolved to "redress the present low representation of women in the economics profession." (See American Economic Association, 1972, p. 447.) Clearly, there are both demand- and supply-side factors operative in occupational segregation. However, this paper deals only with the supply side. For in our view, to successfully reduce occupational segregation, it is critical to understand the supply-side factors which induce women to seek careers in economics and assist them in completing their graduate training. The results described here are based on the 1974–75 *CSWEP*, *AEA* Survey of Economists and should be considered preliminary as data collection is still underway.[1]

I. Career Aspirations

When and why do women decide to become economists? About three-fourths (74 percent) of the women in our sample made the decision to become an economist during college. Only 3 percent made that decision before they entered college and about 24 percent after college (13 percent during graduate school and 11 during post-college employment). These patterns contrast with those in Helen Astin's study, which found that one-fourth of the women doctoral recipients for 1957–58 knew what field they would specialize in even before they completed high school; with a study by Rita Stafford of outstanding women in New York state, which found that 26 percent of the lawyers and 45 percent of the physicians had made their career decisions before they entered college; and with a study by Erwin Linn, which found that 47 percent of women dentists who were graduates of *U.S.* dental schools had decided to become a dentist before entering college. On the other hand, over one-third of the women in Astin's sample said they had decided on their field after college graduation or during graduate school. It would appear that the timing of the decision by a woman to enter a predominantly male field is quite variable and may be related to public familiarity with the particular occupation.[2] Opportunities to influence career decisions seem to be present during a long period of a young woman's life. It is interesting, too, that, although most women economists waited until college to make a *specific* career choice, almost two-thirds (60 percent) had decided while still in high school that they would have a career. And of these, 50 percent planned to pursue nontraditional careers.[3]

---

[1] Information on the sampling and survey procedure and quality of sample may be obtained from the author. Preliminary data used in this article are based on 678 of the 710 questionnaires returned by 55 percent of the women economists registered with *CSWEP*, *AEA*. (Thirty-two women who indicated they had no primary field in economics were excluded.) Each woman economist was requested to supply the names of three male economists who were in her class when the woman did her highest level of academic work in economics. From those names supplied, one name was chosen at random. There are 130 men in the matched sample. The numbers of men and women in the matched sample who have Ph.D.s are unequal because some of the men, matched with women at the bachelor's or master's level, later went on to receive Ph.D.s.

Which persons and factors influenced women's career aspirations during their high-school years? Seventy percent of the women in our sample indicated that they had at least one important role-model in high school. Half of the women had at least two such persons and about one-third had three. For those who had at least one role-model, the most frequently mentioned were a parent (44 percent), or a teacher, administrator, or employer (35 percent). Other relatives and friends were less frequently mentioned role-models.

In about 49 percent of the cases, the most important high-school role-models were men; in about 46 percent women; and in 5 percent both. Where a teacher, administrator, or employer was the most important role-model, the individual was a man in about half (53 percent) of the cases. However, where a parent was the most important role-model, it was the woman's *father* who was the most important influence in 81 percent of the cases. Thus, of those women economists who had an important role-model during high school, only 6 percent saw their career plans as primarily influenced by their mothers. And this was despite the fact that 42 percent of our economists had working mothers who were highly educated and whom they wished to emulate. (Of those whose mothers were employed, 60 percent said they saw their mothers' experience in working outside the home as something they wished to emulate.) Perhaps the fact that these mothers were largely (62 percent) in traditional occupations made them less influential for their daughters.[4]

The ability of the majority of women economists' families to finance their daughters' aspirations, at least through college, should not be minimized. Women economists have relatively highly educated fathers who, presumably, earned relatively high incomes. In our matched sample, there is a significant difference (at the 3 percent level) in education levels between the fathers of men and women economists.[5] A greater percentage of the fathers of women economists are college graduates (17 percent for the women as against 13 percent for the men), have some graduate school training (9 percent versus 1.5 percent), and hold a graduate degree (29 percent versus 23 percent). Also there is a significant difference (at the 1 percent level) in education levels between the mothers of women and men economists. A greater percentage of the mothers of women economists have some college training (30 percent for the women versus 17 percent for the men), are college graduates (19 percent versus 11 percent), and hold graduate degrees (14 percent versus 9 percent). In his study of science doctorates, Lindsey Harmon also found that the fathers of women doctorates were more highly educated than those of men doctorates, and John Folger, Astin and Alan Bayer, in their study utilizing the Project Talent Data Bank, found that "socioeconomic background is more important for girls than for boys in determining college completion and entry to a professional occupation" (p. 287).

---

[2] Only 5 percent of the men in the matched sample made the decision to become an economist before they entered college.

[3] Accountant, mathematician; engineer, architect, physical or life scientist; physician, dentist, pharmacist; social scientist; college teacher; lawyer, politician; manager or administrator; entrepreneur.

[4] Traditional occupations are: librarian; nurse, dietician, home economist; therapist, health technologist; social or recreation worker; nursery, elementary, or high school teacher; sales worker; clerical worker.

[5] A Chi-square test was used to calculate differences between male and female economists.

For those women who had role-models in high school, the most important lessons they seem to have learned from their "mentors" were: that a career can be interesting and fulfilling (87 percent); to seek a high degree (63 percent); and to seek a highly paid job (58 percent). One set of skills they indicated they did *not* frequently learn was how to manage simultaneous family and career responsibilities. And indeed, given our societal mores, perceived potential difficulties or actual difficulties with dual responsibilities may be one reason why, in our matched sample, the percentages of women who are single (26 percent) and divorced or separated (12 percent) are so much higher than the percentages of men (12 and 6 percent, respectively).

As noted earlier, 77 percent of our sample had decided to be economists by the time they had graduated from college. And, indeed, 67 percent of the women majored in economics in college. Clearly, influences during the college years are central to explaining women's decisions to pursue an economics career. Which persons and factors influenced women's career decisions during their college years?

Eighty percent of the women in the sample said there was at least one person during their college years who exerted an important influence on their decision to pursue a professional career. Of those who had an important influence, it was most often (56 percent) a professor, employer, or college/university counselor; frequently (25 percent) a parent; and less often a relative, friend, spouse, or fiance. Sixty-one percent of the most important college influences were men.

While in college, about 30 percent of the women knew a person who tried to *dissuade* them from pursuing a professional career. In 40 percent of the cases, the dissuader was a parent, but teachers and employers accounted for 20 percent of the dissuaders, near relatives for 17 percent, and friends for 13 percent. Less often (7 percent) fiancés or boyfriends, or husbands (4 percent) acted as dissuaders. In 51 percent of the cases, the dissuaders were men; in 43 percent, women; and in 7 percent, both. Only 10 percent of the men in the matched sample knew someone in college who tried to dissuade them from pursuing a professional career.

Why, specifically, did the women in our sample choose to become economists? At the time they decided they wanted to be economists, 45 percent of the women in our sample said they made this decision because they liked the subject matter of the discipline (i.e., they "found it interesting" or "liked economics courses"). An additional 14 percent were attracted to economics because they perceived that they could use the subject matter to help people or solve social problems, and 7 percent chose to be economists in order to utilize their interest in mathematics. However, despite the fact that they chose to deal professionally with economic concerns, only 14 percent of the women in the sample chose to be economists primarily because of economic factors, i.e., attractive salaries or job opportunities. An additional

9 percent of the women mentioned attractive salary or job opportunities as a second important reason for becoming an economist. The ability to solve social problems or help people was mentioned as a second important reason for becoming an economist by 9 percent of the women and ability to apply mathematics as a second reason by 5.5 percent.

In the matched sample, we find no significant differences between men and women with respect to their motivations for choosing to become economists. Forty percent of the women and 36 percent of the men became economists because they liked the subject matter. However, the men more frequently mentioned job and salary opportunities as their most important reason for choosing economics (15 percent) than did the women (8 percent) and the women more frequently mentioned "to solve social problems" and "help people" (18 percent) than did the men (15 percent).

Although the ability to utilize mathematics was not often a major reason cited for choosing a career in economics, nonetheless the women in our sample had a strong mathematics background. In high school their mean number of years of mathematics was 3.4. This is an important finding, for it supports those who observe that the absence of a strong mathematics background can inhibit women who might otherwise choose to major in economics. In college, too, many women economists studied a good deal of mathematics. About 80 percent studied statistics, 63 percent calculus, 30 percent matrix algebra, and 30 percent "advanced" mathematics. In the matched sample, there were no significant differences between the percentages of women and men who studied these four subjects.

What types of colleges and universities did the women in our sample attend? The majority of women (58 percent) went to private colleges or universities, and most (75 percent) attended a coeducational school (either private or public). However, a substantial minority (26 percent) attended a single-sex school. This finding is noteworthy, as there is considerable literature on the value of single-sex schools in influencing women to pursue professional careers. (See, for example, Elizabeth Tidball.) Also, recently, there has been some evidence that women are more likely to major in economics at an all-girls college than in a coeducational setting (Bell 1974).

If we classify institutions by quality, we find that only a very small proportion of women undergraduates (8 percent) attended a school where the economics department was one of the top seven in the country.[6] In part, this is because several of the undergraduate schools with which the top seven departments are associated are, or have been, all male. Twenty-one percent of those in the sample went to schools in the so-called Chairman's Group or to a top-ranked British or French institution; 17 percent attended a top-ranked small, undergraduate college; and 12 percent went to schools at which the American Association of University Professors gave its highest or second-highest ranking for full professors' salaries. Thirty-eight percent went to none of these types of schools but to some other institution.

---

[6] Institutions were divided into five categories. The first category consists of the seven schools which, according to the Cartter Report, have the top economics departments in the country: M.I.T., Harvard, Yale, Stanford, University of California at Berkeley, Princeton, and University of Chicago. The second category consists of schools in the so-called "Chairman's Group," (see Bell 1973) except for the seven included in the first category. Oxford, Cambridge, The London School of Economics, and the University of Paris are also included in category two. Thus, there is a total of forty schools in this category. In the third category are thirteen small undergraduate colleges to which in 1973 the American Association of University Professors (*AAUP*) gave its highest or second-highest (1* or 1) ranking for full professors' salaries: Amherst, Antioch, Barnard, Goucher, Grinnell, Oberlin, Pomona, Smith, Swarthmore, Vassar, Wellesley, Wesleyan, and Williams. The fourth category consists of 132 other schools to which the *AAUP* in 1973 gave its highest or second-highest ranking for full professors' salaries. In the fifth category are all American and foreign schools not in one of the first four categories.

In looking back on their college careers, about 21 percent of the women felt that a narrow perception of their future employment opportunities limited their choice of undergraduate college. Thirty percent felt that a narrow perception had limited their undergraduate course work. However, some men, too, had these feelings, and in the matched sample there were no significant differences between the proportions of men and women who felt that narrow perceptions had limited their choices.

What specialties within the field of economics do women enter? The evidence at hand thus far indicates that there are some differences between the distributions of men and women among the specialties in economics. In comparing the percentage of women in the ten economics specialty fields with the percentage of all *AEA* members (male and female) in these fields, we found a significant difference (at the 1 percent level) in the distribution among fields.[7] A higher percentage of women in our sample were in the fields of labor (19 percent); welfare programs, consumer economics, and urban and regional economics (12 percent); and general economics, theory, and history (19 percent), as compared to the *AEA* membership as a whole (10, 8, and 14 percent, respectively). In the matched sample, among *AEA* members only, there was also a significant difference (at the 4 percent level) in the proportions of women and men in the ten fields. Again, a higher proportion of all women were in the fields of labor (25 percent); and welfare programs, consumer economics, and urban and regional economics (16 percent), as compared to men (9 and 10 percent, respectively). However, this time men were more heavily represented in the field of general economics, theory, and history (26 percent) as compared to women (15 percent). Clearly, the evidence is conflicting with respect to general economics, theory, and history. However, it does appear that women economists are more likely than their male counterparts to specialize in the two fields of labor and welfare programs, etc. These choices may be partly related to the slight, though statistically insignificant, differences in motivations to study economics described above. It should be pointed out, however, that the tendency toward some inequality in distributions among subfields is not nearly as marked in economics as it is in other predominantly male fields, for example medicine and law (see Michelle Patterson).

II. Education and Training of Women Ph.D.s in Economics

In this section we explore three issues in the education and training of women Ph.D.s: financing of degree, interruption of training, and attrition. How do women finance their graduate training? For the total female Ph.D. sample ($N=300$) and for both the men ($N=86$) and women ($N=72$) in the matched Ph.D. sample, fellowships at the predissertation as well as the dissertation stages were a major source of funds for 50–70 percent of our respondents, and in the matched sample, for both stages of study, there were no significant differences between the proportions of men and women who said that fellowship aid was a major or minor source, or not a source, of support. The second important source of support was teaching or research assistantships with 25 to 50 percent of respondents in the several samples listing such assistantships as a major source of funds. However, with respect to assistantships, there was a significant difference between the men and women in our matched sample, with the men much more frequently receiving such aid. For the predissertation stage, the difference was significant at the 6 percent level; for the dissertation stage, at the 1 percent level.

---

[7] These ten fields are those used by the *Journal of Economic Literature*. The percentage of *AEA* members in each field was calculated from the 1974 *Membership Directory*.

Loans represented a relatively unimportant source of funding for women, a significantly more important, though minor, source for men. During the predissertation stage, personal savings represented a minor source of funds for about one-fourth of the women but for almost one-half of the men. At the predissertation stage, support from parents tended to be relatively unimportant in the several samples, except as a minor source for about 20–25 percent of the respondents. No information was solicited about parental support at the dissertation stage. During the predissertation years, employment represented a major source of funds for only 8–10 percent of our respondents. But during the dissertation years, 32–47 percent of respondents in the several samples said employment was a major source of funds.

Support from spouse, as a source of funds, is a relatively complicated variable to analyze. In the predissertation stage, spouse's income was a major source of funds for 15–22 percent of the women and 23 percent of the men; a minor source for 5–10 percent of the women but for 32 percent of the men. For the matched sample, there was a significant difference (at the 1 percent level) between men and women with respect to the importance of spouse's income as a source of support at the predissertation stage. In the dissertation years, spouse's income became more important as a major source for men and women, and more important as a minor source for women, but less important as a minor source for men. But this time there was no significant difference. Part of the reason for the greater incidence of spouse support among men is that a greater proportion of men are married during graduate school. If we look at spouse support for only those who were married during graduate school, we find that at the predissertation stage men still used spouse support more frequently as a source of funds ($p=.01$). However, at the dissertation stage, spouse support was a more important source of funds for women than for men, although the difference was not statistically significant.

Why do women interrupt their Ph.D. studies? About half of the women in the Ph.D. sample interrupted their graduate studies at least once. Of those who indicated how long their interruptions delayed the completion of their dissertation, 17 percent said less than one year, about half (47 percent) said one to three years, 18 percent three to five years and 17 percent more than five years. About 43 percent of the respondents said that having to support their family was a major reason for interrupting their studies; 24 percent said they stopped graduate work for other family-related reasons; and 17 percent said they stopped because of lack of motivation.

Despite interruptions, women Ph.D.s completed their degrees relatively quickly, the mean length of time being 5.7 years. This figure compares quite favorably with the 9.6-year average for the social sciences (male and female 1957–64) cited by Folger, Astin and Bayer (p. 192) and is not substantially different from the 5.3-year average for the men in our matched sample. The 5.7-year figure is even more interesting given the fact that 52 percent of the total female sample were married before completing their degree and one-third had their first child before completing their degree.

Related to the issue of study interruption is the issue of Ph.D. attrition. Why do women Ph.D.s "drop-out"? One hundred and twenty-nine women in our total sample began Ph.D. course work, but did not finish and do not expect a Ph.D. degree.

Because the training of Ph.D.s is extremely costly, from the point of view of institutions as well as individuals, it is useful to inquire into the reasons for Ph.D. attrition. Twenty-seven percent of our "drop-outs" said they left their studies mainly because their interests changed; 23 percent mainly because they decided that, in terms of future financial rewards and/or job opportunities, the work required for the degree "wasn't worth it." Eighteen percent left mainly because of family-related reasons, 8 percent mainly because of an inability to do the required work, and the rest for miscellaneous reasons. When asked "Was there anything that could have been done that would have changed your decision to stop your studies?", 71 percent answered "yes." Financial aid was often (20 percent) mentioned as something which could have changed their decision. But the modal response (36 percent) concerned nonfinancial department support (encouragement, allowing part-time attendance, discussion of job opportunities for Ph.D.s, etc.). Joseph Mooney, in his study of Wilson Fellows' Ph.D. attrition, noted an inverse relationship between graduate school size and the proportion of graduate students acquiring a Ph.D. To the extent that large schools are impersonal and fail to provide much encouragement to students, our finding is related to Mooney's. The discussion of Ph.D. attrition by Michelle Patterson and Lucy Sells also points to the importance of encouragement in decreasing Ph.D. attrition.

III. Conclusion

Given the preliminary nature of our analyses and results, the policy implications of our findings need to be stated cautiously. Yet, for the purpose of reducing occupational segregation, three suggestions can be made even at this early stage of our study.

(1) The high-school years are important for women's commitment to a career. We should arrange more frequent discussions between people in currently male-dominated professions and high-school girls.

(2) Most women become economists because they find that they like the subject matter. Methods of interesting more women in taking some economics courses should be widely discussed.

(3) At the Ph.D. level, women interrupt their studies most frequently in order to help support their families. When they drop out of Ph.D. programs, they feel that better financial aid and more encouragement (financial aid is itself one form of encouragement) could have induced them to continue their studies. The possibilities of significantly increasing teaching and research assistantships as well as departmental support for women graduate students should be seriously considered.

Two Supply Curves for Economists? Implications of Mobility and Career Attachment of Women

By BARBARA B. REAGAN*

The pool of women with highly specialized training is increasing and the tolerance of such women for accepting occupational segregation and narrow views of their career potentials is diminishing. It is crucial that we understand the differences between labor markets for men and women at professional levels, the resulting differences in career patterns, and how barriers to full career development for women impinge on occupational rewards. Only then can we plan effectively for the generation of young women to come. Particularly important at this time is analysis of the market for fields and occupations that are atypical for women.

Overall societal attitudes toward the proper role of women are evolving, yet on the demand side employers' perceived differences as to the employability of women (whether real or imaginary) result in barriers that vary in intensity by occupation. Economics, a stereotypically male profession, has relatively intense barriers for women on the demand side over and above variations in aggregate demand.[1] The demand-side barriers are different from those associated with stereotypically female occupations.

On the supply side, barriers to full career development for women are likely to be those common to all professional occupations plus the effect of women's perceptions of the intensity of the demand-side barriers for the particular profession (i.e., any lack of support of male colleagues, professional isolation and lack of access to information network, or employers' lack of perception of the women's career potential). One group of supply-side barriers includes presence of children, husband's unfavorable attitudes, guilt feelings of the women related to a high sense of responsibility for monitoring consumption at home, and poor earlier education choices based on limited perception of career possibilities. In addition, the two probably most important are geographic mobility or immobility, related to demands of family, and lack of the on-the-job-training, caused by either gaps in the women's career patterns or diminished opportunities for investment in human capital for women when working.

The purposes of this paper are to use preliminary data from the Committee on the Status of Women in the Economics Profession (*CSWEP*), American Economic Association (*AEA*) 1974–75 Survey of Economists to test a model showing that two supply curves exist for economists, instead of one, with the division related to nonpecuniary returns for women, and then consider whether more than two supply curves should be formulated to allow for whether workers are major earners in the family, equal earners, or secondary earners.[2] The model used as a starting point, with subsequent extensions tentatively proposed, is that recently suggested by Nancy M. Gordon and Thomas E. Morton.

I. Comparison of Male and Female Classmates for Highest Degree in Economics

The typical woman economist started work on her Ph.D. when she was a year older than her typical male classmate.[3] The chances are greater that she worked when a B.A. was the highest degree than for her male classmate (62 percent and 44 percent, respectively), and the chances were slightly higher that she worked in a noneconomist job (22 and 14 percent, respectively). She took about half a year longer to finish her Ph.D. than her male classmates, although the difference is not statistically significant with this size sample. This typical woman economist has *not* had a gap of six months or more in her work history since her Ph.D. She has *not* given up a job she liked and moved because her husband changed jobs, moving to another area. Her present salary is $16,500; her male classmate's salary is currently $18,900, or about 15 percent higher than hers.

It has been suggested that persons with large amounts of predegree experience and who take longer to get their Ph.D.s will have a flatter earnings profile and thus a lower salary for any given number of years of experience.[4] The late start (about one and a half years) of the typical woman Ph.D. economist in our preliminary matched sample probably can only explain a small part of the $2,400 difference in pay seven years later.

Untangling the causes and results from differential labor market activity is far more complicated than could be prepared in the three or so weeks since the preliminary data became available and needs the full sample of male economists. However, a few suggestions are possible looking at the first preliminary averages.

II. Model to be Explored

In contrast to previous studies of blue-collar markets, Richard B. Freeman found that the market for college-trained manpower tends to operate "in accord with economic theory, with an informed group of suppliers responding to economic incentives and salaries determined, albeit with a lag, by supply and demand" (p. 36). However, Freeman's study explicitly lays to one side the questions related to women and considers only men in professional occupations.

Gordon and Morton, on the other hand, continued Kenneth Arrow's tradition by considering alternative imperfections in the hiring market and proposed a model of wage discrimination based on the fact that the women's supply curve facing the firm is steeper than the men's. The more steeply

---

Preliminary data from the *CSWEP, AEA* 1974–75 Survey of Economists used in this article are based on the 710 questionnaires returned by 55 percent of the women economists registered with *CSWEP, AEA*, and the first 264 male economists in matched cohorts. (The education cohort was selected at random from three names supplied by each woman economist of men who were in her class when the woman did her highest level of academic work. A name for the employment cohort was supplied by each woman, using an alphabetic criterion, of the male economist at her institution who holds the same rank or approximate level of job responsibility.) Data collection continues for men selected at random for the education cohort from the *American Economic Review, 1974 Directory of Members.* This article, with the exception of the last section, is based on the 52 percent of the women and 67 percent of the men in the education cohort who had completed their Ph.D.s and had worked as economists at least one year. (The numbers of women and men in this matched group are unequal because more of the men matched at the bachelor's or master's level later went on to receive Ph.D.s.) The final section is based on the women and men in the education and employment cohorts who worked in academic jobs in 1974–75.

[3] Subsequent analysis should disaggregate the data by age cohorts to examine how the recent Ph.D.s differ from the more experienced economists.

[4] See G. E. Johnson and F. P. Stafford. They did not consider the effects of fewer on-the-job training or advancement opportunities for women than for men.

sloping supply curve for women that they postulate is based on: (1) differentially perceived nonpecuniary returns from employers by men and women; and (2) higher costs of job search for women than men. The result is that the equilibrium position of the firm is to hire women until the marginal female wage rate, plus the incremental wage bill necessary to bribe male employees to work with the additional women, equals the male wage rate (and marginal revenue product). This model also assumes that men prefer their coworkers or superiors to be men, which widens the resulting wage differential between women and men.

It had previously been noted that incomplete information in the labor market results in transient monopsony power for the firm. Gordon and Morton suggest that permanent monopsony power results from differentially perceived nonpecuniary returns and search costs. Those workers who perceive that a firm will offer greater nonpecuniary returns will work for that firm for a lower monetary wage, thus generating an upward-sloping supply curve. Two types of nonpecuniary returns are suggested to affect women more strongly than men: (1) to the extent that women who are married feel that their job mobility is restricted to the geographic area in which their husbands work, they get nonpecuniary return from an employer in that area and will accept a lower monetary rate from him; (2) to the extent that women have the ultimate responsibility for children, even with household help, women prefer jobs close to their current home more than do men. Even among divorced parents, women still tend to have custody of the children more than men.[5]

III. Test of Model

A. Mobility

Evidence from the *CSWEP* survey for the preliminary group of economists who were classmates for highest degree and subsequently completed their Ph.D.s in economics supports the model that restricted mobility of married women economists is an important factor affecting supply. The fact that for the most part the market for economists is a national one makes mobility all the more an important factor in the supply of women economists. Two-thirds of the women economists with Ph.D.s in the matched sample were married and currently living with their husbands and half had children.

About 60 percent said that spouse's job mobility or immobility had been a major or a minor problem to their career development, with nearly 25 percent saying that it had been a major problem. Furthermore, 30 percent reported that they had given up a job they liked and moved because their husbands or other relative needed to live in another area. More than 10 percent had moved two or more times. Of those who moved for such reasons, the average length of time to find a new job was four months; and 40 percent felt that the new job was worse than the former job, 33 percent felt it was about the same, and 27 percent thought the new job was better.

Often a young married woman is concerned not only about achieving success but also about the effect of her success on her husband. This may particularly be a problem if both are in academics or both are in the same field. "One way of insuring that the academic husband's status will be higher than his academic wife's is to allow the husband's job opportunities to determine where the family lives" (Patricia Albjerg Graham, p. 167).

Men are far less affected by spouse's job mobility or immobility. Less than 25 percent of the male economists had found spouse's job mobility or immobility to be either a major or a minor problem in their career development, and only 8 percent had found it to be a major problem. Furthermore, only 5 percent of the male economists had given up jobs they liked and moved because their wives or other relatives needed to live in another area.

---

[5] In a study of women doctorates, Helen Astin (p. 150) found that "getting adequate domestic help" along with "employer discrimination" were the two greatest barriers to career development, and the third was "husband's mobility." (The first and third are supply-side factors; the second is on the demand side.)

In spite of the fact that so many more women than men feel constrained in their geographic mobility, when the cohorts of classmates were asked whether they would in the next two years be willing to move to a job more than 100 miles away from their present job provided it carried more responsibility and at least 15 percent more salary, 28 percent of the women said "yes" and another 14 percent said "probably yes." Men when asked this question said "yes" 32 percent of the time and "probably yes" 23 percent. Conversely, 45 percent of the men were unwilling to move in the next two years. Thus, it is incorrect to assume, as some employers do, that all women are immobile and all men are mobile.

On the demand side, in employers' minds the effect of perceived immobility of women is much greater than for men. Over a fourth of the women economists with Ph.D.s reported that in the last three years when they have been interviewed for jobs, questions related to their spouses and/or domestic situations appeared to be important considerations in the minds of the potential employer. Only 3 percent of the men so reported.

We have a long way to go before attitudes of male employers change and they are able to consider people as individuals who will themselves measure the tradeoffs involved. Instead, many male administrators are still feeling that they do not want to be party to weakening the bonds of matrimony for someone else's marriage (i.e., interfering with another male's property rights).

B. Care of Children and Home

The nonpecuniary return to women from jobs close to home is shown indirectly by responses to one other question. So far in our society women have the ultimate responsibility for children and home, and this is seen by a large proportion of women as a barrier to career development. More than a third of the women Ph.D.s said that the fact that they had to devote a large amount of time to administering consumption (care of children, house, etc.) had been a major problem in developing their careers fully. More than 70 percent said it was a major or a minor problem. Of the men, however, only 8 percent found such home responsibilities a major barrier to career development.

The 50 percent of the women Ph.D.s who have children average two children per family. The costs of caring for children increase job search costs for women more than for men, as well as being a basis for women perceiving nonpecuniary return from jobs close to home.

C. Distaste

The additional assumption of the Gordon-Morton model that men dislike working with women as peers or as superiors affects the wage differential in that men's wage rate would then be an increasing function of the proportion of women hired. The reasonableness of this assumption for men and women economists is shown by the fact that 29 percent of the women Ph.D.s reported that in the last three years an employer indicated in the female respondent's presence a preference for hiring a man economist rather than a woman economist. In addition, 16 percent of the men surveyed also reported that an employer had stated in their presence a preference for a male economist over a female.

Indirectly, the extent of distaste can be seen from the high proportion of women Ph.D.s who reported that social or professional isolation had been a barrier (56 percent for women and 28 percent for men), and from the fact that 42 percent of the women reported that lack of support from colleagues had been a major or minor barrier to career development. (Only 1 percent of their male classmates who got their Ph.D.s reported that lack of colleague support was a major problem and 14 percent that it was a minor problem).

On the demand side, employers often reflect their understanding of male worker distaste for women colleagues or supervisors by failing to see women as having the potential for special assignments, on-job training opportunities, or professional development into department or agency administrators. It should be noted, however, that some or even much of their reflected distaste may be an erroneous reading of the situation or an oversimplified projection of the administrator's own biases. Nevertheless, about 10 percent of the women Ph.D. economists compared with only 1 percent of their male cohort reported that employer's lack of perception of their potential had been a major barrier to their career development, and another 33 percent of the women, but only 15 percent of the men, reported that it had been a minor barrier.

IV. Extension of Model

A. Discontinuities in Career Patterns

There is another set of circumstances that might work in the opposite direction to those suggested so far in this paper and result in decreasing the slope of the supply curve for women more than for men. If so, this would reduce the wage differential between men and women. This set of factors is related to years of experience and discontinuity in career pattern. To the extent that women at lower wage levels (primarily non-Ph.D.s in academic jobs) have career patterns with major interruptions for childbearing and rearing, the supply of women economists at lower wages is decreased. At upper wage levels the supply might not be decreased because higher salaries permit hiring competent housekeepers and child care arrangements. The net effect, therefore, could be to lower the slope of the supply curves for women. Preliminary data from the *CSWEP* survey suggest, however, that the slope of the supply curve for women economists is not greatly affected by major gaps in their careers.[6] Thus, this factor would not explain much of the male-female wage differential.

Of the economists who now have Ph.D.s, 24 percent of the women had one or more gaps of six months or more in their work history when their highest degrees were B.A.s or M.A.s for reasons other than further education (compared with 2 percent of the men). About five-sixths of these gaps were for demands of home or spouse or personal reasons. The other major reason was "inability to find suitable job." Some of these gaps are undoubtedly tied to moves to new areas when husband moved.

Another 20 percent of the women (but only 1 percent of the men) had gaps of six months or more after they received their Ph.D.s when opportunity costs were higher and higher incomes made paid child care more feasible. The average length of gap after the Ph.D. was two years for the women who had career gaps. Again, most of the reasons were to meet demands of home or spouse and the remainder, no suitable job.[7]

---

[6] Jane W. Loeb and Marianne A. Ferber (p. 247) in their study of the status of women faculty at the Urbana-Champaign campus of the University of Illinois found little difference between men and women with respect to years of professional experience or years of academic experience once age and year of degree are considered. (The faculty study was not limited to those with Ph.D.s.) For women doctorates, a strong pattern of discontinuity was not observed by Astin (pp. 156, 157). Of those women receiving Ph.D.s in 1957 and 1958, 91 percent were in the labor force seven or eight years later. Of these, 81 percent were working full-time and only 10 percent part-time. Nearly 80 percent had never interrupted their careers, and for the rest the median interruption was only fourteen months.

The career commitment of the women Ph.D. economists appears to be as strong as their male classmates who get Ph.D.s. Similar proportions of females and males have worked as economists half or more of the elapsed time since their B.A. degrees (84 and 82 percent, respectively). Over 90 percent of the females are currently members of the *AEA*, compared with 85 percent of the males. Ninety-one percent of the women see their work history as a development of a career rather than just a series of jobs. The corresponding proportion for males is only a little higher, 95 percent; this is not a statistically significant difference.

B. Relative Earning Position Within Family

When sex has been used in past empirical work on labor force participation, it often has been used as a proxy for the relationship of earners within the family with the expectation that women are secondary sources of family income. This is not always the case.

Another fruitful way of looking at labor force participation is to consider the relative proportion of family earnings contributed by the wife and the husband. It might be expected that women who were the major family earners (single or married) would have labor force behavior more like men who are also the major earners (single or married). It might also be expected that the behavior of these major workers (male or female) would differ from that of women who were the minor earners in the family. Furthermore, the behavior of men and women who were essentially equal earners (say, contributing 40 to 60 percent of the family income) would again differ.

Although more refined analysis is needed with the larger sample, a few points are suggested from the first estimates now available. (See Table 1.) These data refer to economists with academic jobs in 1974–75, excluding those with business, government, or other nonprofit positions, but they are not limited to economists with Ph.D.s.

The two groups of women who are major or equal earners are for the most part similar. They in turn differ from the women who are minor earners in the family.[8] The women who are minor earners took longer to obtain their Ph.D.s, nearly always have found the need to devote large amounts of time to administering consumption to be a problem in career development, are not as mobile in terms of the current job market, have more often in the past given up a job they liked and moved because a spouse or relative needed to live in another area, and more often have had gaps in their work history of six months or more. The question immediately arises as to which is the direction of causation. Are their earnings lower because of their slow start, their immobility, their lower on-the-job training, their conflict with home and job demands, or is their labor market behavior in subordinating their career to their spouse's rational behavior considering relative earnings?

The differences in these selected items

---

[7] Gaps in careers affect not only the supply curve but also decrease the amount of on-job training. A high turnover rate in jobs would also decrease the amount and quality of on-job training possible. In the years since they received their Ph.D.s, the women averaged 2.2 jobs, whereas the men averaged 1.4 jobs. However, this difference is not statistically significant at the 95 percent level with this size sample.

[8] Several studies have shown that single women have a less difficult time in career development, i.e., they earn more and are hired for more lucrative jobs.

TABLE 1—LABOR MARKET ACTIVITY AND CAREER BARRIERS BY TYPE OF EARNER, BASED ON RESPONDENT'S CONTRIBUTION TO FAMILY INCOME IN 1973–74

(Economists employed in academic positions in fall 1974)

Item	Major earners (>60%)		Women Minor Earners (<40%)	Women Equal Earners (40–60%)
	Women	Men		
Number in preliminary sample	66	196	27	37
Percent married and currently living with spouse	35	88	100	100
Respondent's proportion of total family income:				
Under 30 percent	0	0	57	0
30–39	0	0	43	0
40–49	0	0	0	54
50–59	0	0	0	46
60–69	58	35	0	0
70–99	25	33	0	0
100	17	52	0	0
Highest degree in economics (percent):				
B.A.	3	4	0	0
M.A.	8	5	7	3
A.B.D.	20	9	7	11
Ph.D.	68	82	85	86
For those with Ph.D.:				
Average number of years to complete Ph.D.	5.0	5.3	7.5	4.8
Average age when completed Ph.D.	30.8	31.2	33.4	29.6
Percent who perceived the following as problems in developing careers fully:				
Need to devote large amounts of time to administer consumption (child care, house, etc.)	56	46	93	72
Major problem	24	8	67	23
Minor problem	32	38	26	49
Spouse's job mobility or immobility	52	22	52	64
Major problem	36	4	26	22
Minor problem	16	18	26	42
Lack of support from colleagues	44	20	20	47
Major problem	13	2	0	12
Minor problem	31	18	20	35
Social or professional isolation on job	57	33	40	64
Major problem	21	7	0	28
Minor problem	36	26	40	36
Current job mobility:				
Percent who would be interested in change of job now	49	44	27	48
Percent who in next two years would be willing to move to a job 100 or more miles from present job providing it carried more responsibility and at least 15 percent more pay than present job	35	35	12	26
Previous job mobility:				
Percent who gave up job liked and moved because spouse or relative needed to live in another area	22	4	46	31
Percent with one or more gaps in work history of six months or more for reasons other than further education:				
With B.A. or M.A. as highest degree	12	6	30	31
After Ph.D.	9	0	26	12
Average length of gap after Ph.D. for those having gap (years)	1.9	—	3.2	4.8

Source: Preliminary data from *CSWEP, AEA* 1974–75 Survey of Economists.

between women and men who are all major earners, either single or married, suggest that sex is still needed as a stratification variable in addition to type of earner. The major career barriers reported by women who are major earners are significantly different from those reported by male major earners. Furthermore, many women economists who are either major or equal earners at this time appear to have subordinated their careers to those of their husbands at one or more previous decision points. Such is the effect of long-standing custom.

V. Conclusions

Preliminary data from the *CSWEP, AEA* 1974–75 Survey of Economists suggest that the supply curve for women economists is more steep than the curve for men because of nonpecuniary returns from employers perceived by women. In addition, men's attitudes toward women colleagues are seen as barriers that have impeded full career development for women economists and thus exacerbated the resulting wage differential. These effects undoubtedly are further deepened by women's reduced will to bargain due to their perception of the effects of previous societal conditioning of colleagues, employers, and themselves. Among women and men economists with Ph.D.s, there are differences in continuity of career patterns both before and after the doctorate is received. These probably are not great enough to change the above conclusion that differences in the supply curve will lead to lower salaries for women, although more detailed analysis is needed.

Supply curve specification should consider not only stratification by sex but also whether workers are (1) major or equal earners in the family or (2) minor contributors to family income.

While more careful analysis of differences in the rewards (salary, rank, and tenure) as functions of various factors must await the larger sample of the male cohort of economists, the tentative conclusions of this analysis are borne out by the reported perceptions of the group studied here: 28 percent of the women economists with Ph.D.s felt that they were paid less or had lower level jobs than they would have had if they had been of the opposite sex.

JOINT LUNCHEON ADDRESS

Inflation and the International Monetary Situation

By H. JOHANNES WITTEVEEN*

Today, I thought it might be appropriate for me to say a few words about the nature and causes of the accelerating inflation from which the world has recently been suffering, and in particular about any interrelationships that may exist between inflation and recent developments in the exchange rate system.

A certain degree of price inflation has been pervasive throughout the postwar period. During the 1950's its importance seemed on the whole to be declining, but later the trend was reversed. During the decade of the 1960's, national income deflators in the industrial countries rose, on the average, at an annual rate of 3.4 percent. While the rate of increase fluctuated somewhat, there was a gradual tendency for inflation to gather speed towards the end of the decade. For a year or two this tendency was checked by the recession of 1970 and 1971, but in the following years the acceleration was rapid indeed with price increases of over 7 percent in 1972 and almost 12 percent in 1973 and 1974.

Developing countries have always, on the average, had higher rates of inflation than industrial countries, but the same trend is visible among them: their consumer price indices, which had risen at an average rate of 13 percent during the 1965–72 period, accelerated to 24 percent in 1973 and 35 percent in the early months of this year.

During the 1950's and 1960's those who deplored what was then called inflation could console themselves with the thought that at least it was accompanied by an unprecedentedly rapid expansion in production and rise in living standards. If the inflation had to any extent served to promote the exceptional real growth, it might seem to some not too high a price to pay. In the 1970's, however, a very sinister phenomenon, previously familiar to us only from the history of hyperinflations, has reappeared and recently become acute, namely, the concurrence of steeply rising prices with declining output and rising unemployment. This phenomenon, sometimes termed "stagflation," presents those responsible for economic policies with an excruciating dilemma.

Looking back, it would seem that the present inflation had begun as the normal expression of an excess demand situation evoked by policy responses to a preceding recession. The source of many of our current problems may be traced to the slowdown in economic activity which occurred in 1970–71 in most industrialized countries. Real output expanded rather sluggishly during these two years, averaging 2.7 and 3.7 percent in real terms for the industrialized countries as a group. Government policy subsequently became more expansionary. With hindsight, it is possible to say that the fiscal and monetary policy actions taken were probably too stimulative. For instance, the average rate of monetary expansion in industrialized countries increased from a relatively moderate

---

* International Monetary Fund.

rate of 7 percent during 1969–70 to over 12 percent in 1971 and 1972. This high rate of monetary growth was accompanied by, and to some extent reflected, the pursuit of expansionary fiscal policies in many countries. To this expansion in the monetary aggregates in the various national economies must be added the sharp increase in credit available through the Eurocurrency market. The estimated size of the Eurocurrency market increased from $44 billion at the end of 1969 to $132 billion, or almost 15 percent of the world monetary stock, at the end of 1973. This must have contributed in no small measure to worldwide inflationary forces.

As a consequence of the stimulative actions taken during 1971–72, the world economy entered a phase of strong expansion in 1972–73. During these two boom years the rate of real *GNP* growth averaged 6 percent, a rate that was not sustainable on a long-term basis. As bottlenecks and capacity constraints were reached, excess demand pressures built up quickly and contributed to the price increases to which we have referred.

Though the current inflation began and gathered strength under the stimulus of demand pressure, there seems little doubt that in its latter stages it has been aggravated and accelerated by cost-push factors, some of which, in turn, have arisen from particular features of the demand inflation. It is these cost-push factors which, in turn, have been responsible for the coincidence of inflation and declining output.

Thus, the boom of 1972 and 1973 had a particularly strong effect in raising prices of foodstuffs and raw materials. Long-run factors, such as rising population and rising per capita income, may have been tending to expand demand for agricultural products faster than the trend growth of supply. However that may be, supplies have recently been curtailed by a series of bad harvests. Consequently, agricultural stockpiles were reduced. Their disappearance removed a factor which had served to mitigate the price-raising effects of past periods of industrial expansion. The elimination of the stockpiles served as a signal to speculators that future shortages would find expression in price changes rather than in sales from existing stocks.

The rise in the price of foodstuffs and most other primary products, though of unusual magnitude, must itself be regarded as an aspect of demand-induced inflation. The same cannot be said of the sharp increase in crude oil prices at the end of 1973 which added another powerful impetus to world inflation. Petroleum is the single most important commodity in world trade and its widespread use as an industrial input, as well as a consumer good, affects wholesale and consumer price indices directly. It has been estimated that the direct impact of the crude oil price increase added some 2 to 3 percent to world prices.

The soaring flight of primary product prices arising from these causes would appear to have stimulated an increase in the prices of finished products greater than could be accounted for by its direct effect on costs. It has done so by evoking increases in other cost elements to a greater extent than could be justified by demand conditions, thus magnifying and accelerating the inflation.

Thus, labor has generally been unwilling to accept the drastic reduction in real income growth—or even absolute decline in real income—which the rise in primary product prices would tend, under market principles, to require of it. And this reluctance has understandably been enhanced by the increases in paper profits which the inflation itself, in conjunction with conventional principles of cost accounting based on historic costs, has tended to bring about.

Another important element in this connection is indexation. Many wages and social benefit payments had been indexed during the late 1960's and early 1970's when we experienced an inflation that was relatively mild compared to our present situation. Often, these contracts contained threshold clauses, providing for increased wages or benefits only after a certain price index had increased by a stipulated percentage. The accelerating price inflation in 1973 triggered many of these clauses and consequently costs to business enterprises and governmental expenditures for social benefit payments increased. At a late stage in inflation, when price expectations, enhanced by an uncertainty factor, are tending to exceed actual inflation, indexation may play a part, in conjunction with demand management, in bringing the process to an end. At an earlier stage, however, its influence almost certainly runs the other way.

As regards profit margins, two opposing forces have probably been at work. Insofar as firms have based their pricing policies on historic cost or insofar as price controls, where they exist, have been administered on this basis, price increases may have been temporarily mitigated or held back. There has, however, been a very natural, and indeed desirable, tendency for firms to shift their pricing policies to a replacement cost basis even where national authorities have been reluctant to reckon taxable profits in this way. On the other hand, the widely practiced system of percentage markups as such is obviously one which tends to multiply the price-raising effects of any increases in costs of materials or labor, whether these increases are a reflection of demand-pull or cost-push factors. Where the total amount available for distribution between capital and labor in industry has been diminished by the rise in primary product prices, the combination of linking wages to the cost of living and the application of percentage price margins by employers sets up a perfect mechanism for the production of a wage price spiral.

The system of direct taxation in industrial countries, both on account of its progressivity and of its adherence in some countries to historic cost accounting principles, tends, of course, to act as a drag on demand inflation. There have been indications, however, that it may be tending to promote cost-push inflation insofar as unions in their wage bargaining and employers in their pricing practices try to maintain a given net-of-tax income. Somewhat ironically, with a progressive tax system the effect of such further inflation will be still further to reduce real after-tax incomes.

As inflation has persisted at an accelerating pace, people have become increasingly more conscious of it, increasingly inclined to expect its continuance, and increasingly desirous of protecting themselves against it. This may even go to the point where economic units not only try to recuperate past losses, but also make an attempt to protect their position against the expected future erosion of their economic position due to inflation by anticipatory price or wage increases. This has naturally given a further impetus to inflation and, together with the factors already mentioned, has contributed to a shortening of the time lags between the various stages of inflation. Thus, we have shorter union contracts, indexation of wage and social benefit payments, flexible interest rate clauses, changes in accounting practices, and other arrangements under which price increases are passed on more rapidly than would otherwise be possible and perhaps even in a magnified form.

All these factors, taken in conjunction, not only contribute to the inflationary spiral but, by accelerating the interaction of price on price, make the system increasingly sensitive to exogenous inflationary shocks. In this context it is easier to understand the magnified repercussions of the increase in oil prices which I referred to earlier.

I do not wish to embark today on the theme of what needs to be done to counter inflationary pressures, or to remedy the stagflation from which we now suffer. I would only sound one warning note, derived from a good deal of International Monetary Fund experience. Partial measures, designed to hold down the price of particular goods and services, such as those which enter prominently into cost of living indices or those produced by the public sector, whether they operate by way of price control or of subsidy, are unlikely to be successful in reducing inflation as a whole and may often stimulate demand. In addition, they usually create scarcities or divert resources from their most appropriate uses. Only comprehensive measures, whether in the field of demand management or of incomes policy or both, will serve.

Thus far, the causes of inflation which I have analyzed have been those which could operate in a closed economy. I should now like to focus on an aspect of the arrangements governing the transmittal of inflationary or deflationary impulses between countries.

It has not escaped notice that the period—from 1973 on—in which inflation has begun to get out of hand in the world is also the period during which floating exchange rates have been the rule rather than the exception among industrial countries. The question is whether this is a chance combination of circumstances or whether there is an interrelationship between the two phenomena and, if so, what it is.

First, a few words on the role of inflation in the abandonment of the par value system.

As we have seen, a moderate degree of inflation prevailed throughout the postwar period, becoming less moderate in the late 1960's. Moreover, the character of the inflation changed somewhat, cost-push elements becoming more prominent. Whereas earlier inflation had been fueled by reconstruction needs and sometimes by the incapacity of governments to finance their expenditures without recourse to the banking system, later the prime motive was to preserve a high level of employment which, given more aggressive behavior of labor, could only be done at rising price levels.

Stable exchange rates can only be combined with desired levels of employment when there is a consistent development of price levels in different countries. Now, abstractly, the mere fact that prices are rising everywhere does not prevent relative national price levels from remaining constant or moving in a direction consistent with international equilibrium. In practice, however, the higher the degree of inflation, the larger are likely to be the divergences in inflation rates. Moreover, there is no reason why such divergences should occur in the direction required by structural changes affecting the balance of payments.

The growing importance of the cost-push element in inflation probably tended to accentuate these divergences and to necessitate exchange rate adjustments. While profits were high and unions unaggressive, countries in payments difficulty could get back into balance by slowing down the expansion of demand without undue effects on employment; when cost-push became the driving element in inflation, this ceased to be true and devaluation became the only solution.

Of course, exchange rate adjustment could take place under the par value system. During the 1960's such adjustments were often unduly delayed, but later, when they became more frequent, the volume of anticipatory capital movements grew too great to be contained within the structure of this system, and resort to generalized floating became inevitable.

A question which is perhaps more controversial than that of the role of inflation in compelling a transition to flexible exchange rates is that of the possible role of the flexible exchange rate system in promoting inflation.

There are various reasons, much discussed in the literature, for thinking that exchange flexibility and, in particular, freedom from the obligation to adhere to any particular exchange rate should make it easier for a country to cope with inflationary pressures and to preserve internal financial stability.

In the first place the option of allowing one's currency to appreciate should enable the monetary authorities of a country to buffer it against the impact of demand pressures from abroad, whether these arise from lax demand policies practiced in other countries or from structural shifts in foreign trade, though in the latter case adjustments will still be required as among particular industries. It should also enable them, though at some cost in terms of exchange stability, to protect the monetary system against an influx of reserves that would otherwise be difficult to offset. The degree of insulation against external shocks that is achieved in this way is reduced by a number of factors. Thus, the more inflationary countries may for a time attract a sufficient volume of investable funds to prevent their exchange rates from falling, and those of the less inflationary countries from rising. Again, the low level of foreign trade elasticities in the short run means that when exchange rates do move the buffer against external demand variations will be fully effective only after a time lag. Nevertheless, the monetary insulation will operate immediately, and I think that countries like Germany or the Netherlands would feel that the regime of floating rates had served to protect them, at least in some measure, against imported inflation. At the same time, it has to be borne in mind that insofar as this mechanism tends to prevent the spread of inflation it also tends to concentrate and magnify it in the countries in which it originates.

A second, though related, advantage of the flexible rate system from the standpoint of stabilization policy is that the instruments of demand management, particularly monetary policy, operate much more powerfully on the domestic economy when they are not subject to the leakages that affect an open economy under fixed exchange rates. Monetary contraction need no longer be frustrated by an influx of reserves and money from abroad and will, by promoting exchange appreciation, exercise a deflationary effect on the current account balance of payments. Here again, some of the deflationary effect will be achieved at the expense of other countries, but these countries have both the incentive and the possibility to follow suit with effective stabilization policies of their own.

Balancing these arguments in favor of flexible rates, there are two arguments frequently advanced against flexible rates from the standpoint of stabilization policy. There is, first, the contention that governments, especially democratic ones, are naturally prone to pursue expansionary policies and that exchange flexibility removes the inhibitions formerly imposed upon this tendency by fear of running out of reserves and of incurring the political odium of devaluation. There is some force in this contention, though the fact that under floating rates the effects of overexpansion must be kept at home with immediate repercussions on the domestic cost of living should provide, to some extent, a substitute discipline, if possibly a less effective one. I must add that there is not much evidence that the transition to floating rates in 1973 has led to a perceptible loosening in demand management. The expansion in money stocks which laid the foundation for the boom took place from 1970 to 1972 which, despite an interlude of floating in 1971, was on the whole a period of fixed rates.

Another familiar argument against floating rates which seems somewhat dubious in practice is the contention that spontaneous inflation pressures within a country, which would, under fixed rates, have been dispersed harmlessly over a wide area where they could be more easily dealt with, might, under floating rates, be "boxed in," as it were, in the country of origin in a way that makes them more difficult to control. This might have some validity under a system of free floating when countries were forbidden to intervene to support the exchange rate, but under the system of managed floating which actually prevails, countries are free to intervene in support of the rate and when domestic inflationary pressures are strong are very likely in practice to do so.

There are, however, some other reasons for suspecting that floating rates may on balance have contributed to the average rate of inflation among countries in the last year or two. Most of these operate from the side of costs rather than of demand. For example, there is the question of the risks attached to international transactions and to the production of internationally traded goods. We have seen some rather large fluctuations in exchange rates since generalized floating began, particularly as between the *U.S.* dollar on the one hand and the currencies participating in the *EEC* snake on the other, where the amount of stabilizing official intervention has been rather small. Thus, the deutsche mark appreciated by some 30 percent vis-à-vis the dollar from February 14, 1973 to July 1973, then depreciated by 22 percent by a date in January 1974. Five months later, by May of 1974, the mark had risen again by 20 percent to a new peak only to fall 10 percent to a new trough in September. Since then it has risen again by nearly 10 percent. It can be argued that these fluctuations have shown a declining tendency. Nevertheless, they have been large and must have added to the risks of doing business, not only as between the two countries in question, but among all those countries whose currencies are tied either to the dollar or to the mark, or even those which try to steer a middle course between the two.

While one can hedge in forward markets against some of these risks, these markets are not well developed for all relevant maturity periods, and the spreads charged on forward contracts are relatively high. Besides, production of international trade goods or investment in such production involves many types of exchange risks which cannot be hedged by short-term forward contracts. Of course, devaluation and revaluation risks would exist under a par value system also; moreover, in some cases the adjustment of exchange rates facilitated by a flexible system will serve to offset other risks, such as the risk of divergent developments in domestic currency costs. But the sort of short-to-medium term fluctuations in rates to which I have drawn attention have characterized the flexible rate system up to now, and it would be strange if required profit margins had not been widened to cover such risks.

These fluctuations probably promote inflation in yet another way. Exchange rates influence the distribution of demand between domestic and foreign products, and rate fluctuations will involve demand shifts which will later in some measure be reversed. These demand shifts may well exercise a ratchet effect on inflation. Given the downward rigidities in wages and prices characteristic of modern industrialized economies, shifts in purchase patterns brought about by the exchange rate changes, or even the expectation of such shifts, may tend to raise prices in the countries of depreciating currency without effecting a corresponding price reduction in the countries of appreciating currency. It might be argued, in view of the slowness with which demand patterns respond to exchange rate changes, that this ratchet effect would not be very important for fluctuations as short term as those to which I have just referred. However, there is evidence that prices are adjusted to meet changes in competitors' prices evoked by exchange rate movements in advance of the expected shifts in demand, and that these anticipatory price adjustments are more marked in the upward direction.

This brief review of the interrelationship of inflation and exchange rate flexibility seems to yield some tentative conclusions. In the first place, the influence of inflation on the exchange rate regime has been more considerable than the influences operating in the opposite direction. As regards the bearing of the exchange regime on inflation, I would say that floating makes it easier for countries with relatively strong anti-inflation policies to achieve the desired results, but that the price for this is more inflation in countries already inflating more strongly. Thus, floating which is partly caused by differences in rates of inflation in its turn increases these differentials.

With respect to the average rate of inflation in all countries taken together, floating exchange rates may have been a slight additional fillip to inflation, particularly through their effect on the risk element.

An important distinction has to be drawn here between the role of the floating technique in permitting prompt adjustment to underlying trends or even to cyclical reactions in the balance of payments and its role in permitting shorter term fluctuations. The first aspect is almost entirely beneficial from the standpoint of inflation control, as indeed from the aspect of adjustment in general. The second aspect is the one that may cause trouble both for stabilization policy and, indeed, for adjustment also.

In a decision adopted last June the Executive Directors of the International Monetary Fund have agreed on a set of guidelines or principles which its members will attempt to follow to avoid disruptive exchange rate movements under floating. The course of action which the guidelines encourage is that of smoothing out day-to-day and week-to-week fluctuations in rates, resisting overrapid movements of rates in any particular direction, and resisting undue deviations in rates from their medium-term norm, if such can be discerned. This would tend to eliminate the additional risk resulting from excessive short-run fluctuation in exchange rates.

In the further development and application of these guidelines I therefore see a possible remedy for any net tendency that may exist for the floating rate system to promote inflation. This argues strongly for the development of the international consultation and cooperation which could make these guidelines effective.

UNDERSTANDING WORLD INFLATION

Monetarist and Keynesian Models of the Transmission of Inflation

By WILLIAM H. BRANSON*

The international monetarist model has a fully endogenous money supply, with the domestic rate of inflation fixed by "the" world rate. A standard post-Keynesian model, on the other hand, includes as endogenous variables both the rate of inflation and the balance of payments, with the monetary authorities controlling the money stock. In this paper I argue that the Keynesian model is more consistent with the facts, and that both the monetary and monetarist models are extensions of the Keynesian model with additional, unrealistically restrictive assumptions.

I. The Monetarist Approach

The monetarist theory of world inflation, and its connection to the balance of payments, goes roughly as follows. The excess of the growth rate of the world money stock over the growth rate of output determines the world rate of inflation. By an extension of the "law of one price," this determines each country's rate of inflation. Given this rate of inflation, and interest rates and output pegged by small-country assumptions, movements in the domestic credit base determine reserve changes. The keys to all this are the condition that money demand equals supply, and the extreme small-country assumptions.

The model can be set out fairly simply, following H. G. Johnson (ch. 3). At the level of the individual country we have a demand function for money,

$$M^D = P\cdot m(y, r), \tag{1}$$

and a supply equation $M=R+B$, where R is international reserves and B is the domestic credit base. Here for convenience I assume a 100 percent reserve system. P is the price level (GNP deflator), y is real output, and r is the interest rate. Equating supply and demand yields the equilibrium condition

$$R + B = P\cdot m(y, r). \tag{2}$$

The small-country assumption for capital markets pegs r to "the" world interest rate. The small-country assumption for goods markets pegs P and y. The country is a price taker on world markets, pegging P, and it can sell all it chooses at P, pegging y. Now with P, y and r fixed by the small-country assumptions, movements in the domestic credit base B determine movements in reserves R, on a one-for-one basis.

The final step is the link from the growth rate of the world money supply to the world rate of inflation. Using a subscript w to denote world level variables, the monetarist story has a world supply and demand equilibrium,

$$M_w = P_w\cdot f(y_w). \tag{3}$$

Here the interest rate disappears from the demand function for money. Taking the world money supply and world output (!) as exogenous, the rate of inflation is given as

---

* Professor of economics and international affairs, Princeton University.

$$(4)\qquad \left(\frac{\dot{P}}{P}\right)_w = \left(\frac{\dot{M}}{M}\right)_w - \epsilon_y\left(\frac{\dot{y}}{y}\right)_w,$$

where $\dot{X} \equiv dX/dt$, and ϵ_y is the income elasticity of the demand for real balances. With (4) determining the world rate of inflation, P (or $\dot{P}/P$) in (2) is fixed, and changes in the growth rate of B simply change the path of R.

This monetarist model has at least two empirical implications. One is that national inflation rates converge to the world rate. The second is that reserve changes offset one-for-one changes in the domestic credit base, with the money stock being completely endogenous. The latter implication is not consistent with the empirical evidence. For example, P. J. K. Kouri and M. G. Porter obtained the following estimates of the R reaction to a B change (from estimated capital flow equations), as a fraction of the initial B change: Germany, -0.77; the Netherlands, -0.58; Australia, -0.47; Italy, -0.43. In the monetarist story, all of these should be insignificantly different from -1.0. R. J. Herring and R. C. Marston obtained similar results for Germany and Canada, and the evidence is accumulating on this point. The evidence on the first implication of convergence is shaky, but here another problem arises: a Keynesian-Phillips view of the world yields the same implication of convergence, as I show below in section III.

One reason why the monetarist model is not consistent with the data thrown up by our short-run world is that the assumptions are not consistent with reality. Even in small open economies we would see "the" interest rate and price level varying relative to the world interest rate and price level, if we could observe such variables in the first place. And we certainly see variations in real output around its trend or full employment path even in small countries. So to understand how inflation spreads, we must go to a model that relaxes these monetarist assumptions. My favorite candidate here is the bare-bones post-Keynesian model of A. S. Blinder and R. M. Solow, with a foreign sector added. The monetarist model is a special case of an augmented Blinder-Solow model with addition of the extreme small-country assumptions.

II. The Keynesian-Monetary Approach

The bare-bones post-Keynesian model has aggregate demand determined by the "textbook" *IS-LM* framework, an aggregate supply curve, and equilibrium reached at the intersection of demand and supply. The internal equilibrium so determined can be related to a schedule showing r, y pairs that yield balance of payments equilibrium to determine the external situation.

The supply curve is simply $P = P(y, \beta)$, with $\infty \geq P_y > 0$. This assumes wage rigidity or money illusion in the labor supply function. Here β is a shift parameter reflecting changes in availability of raw materials, with $P_\beta < 0$. A useful improvement here would be integration of the "Scandinavian" two-sector model of price determination described by O. Aukrust.

Aggregate demand is given by the intersection, at a given price level, of the *IS* curve

$$(5)\qquad E(y, r, \tau) + g + b(P, y) = y,$$

and the *LM* curve

$$(6)\qquad M = P \cdot m(y, r).$$

Here E is private expenditure, τ is the tax rate, g is real government purchases of goods and services, and b is the current account balance. Given g, τ, M and P, (5) and (6) determine r, y at the *IS-LM* intersection. As P rises, the y so determined falls, giving a negatively sloped aggregate demand curve, as shown by C. M. Gambs. The intersection of the supply and demand schedules determines equilibrium P, y, and the interest rate comes from the *IS-LM* intersection with *LM* positioned by the equilibrium value of P.

To determine the external situation, the *IS-LM* intersection has to be related to the r, y line giving balance of payments equilibrium, the *BP* line of Figure 1. If the r_0, y_0 point lies below *BP*, there is a deficit (r is too low, given y). The workings of this model are rigorously derived in Branson (1974).

Several implicit assumptions differentiate this model from the monetarist model. Here it is assumed that the domestic monetary authorities control M—that sterilization of the external balance is possible. Further, it is assumed that home goods and assets are either (a) imperfect substitutes for foreign goods and assets, or (b) partially nontraded. This gives some freedom of movement to P, y and r.

With this framework we can look at the effects of changes in exogenous variables on the home price level and the external balance, which are determined endogenously. An increase in the money stock shifts the *LM* curve, and the demand curve in P, y space, out. This pulls the price level up and increases the balance of payments deficit by moving the *IS-LM* intersection away from the *BP* line. From the point of view of other countries, this will appear as normal imported inflation. Their exports and price level will rise, and they will register a payments surplus.

The effects of fiscal policy are not so clear. An increase in government purchases or a tax cut shifts the *IS* curve and demand curve out, increasing y and the price level. But the effect on the balance of payments is unclear, as noted originally by J. M. Fleming. If the *BP* line is steeper than *LM*, the expansionary fiscal policy increases the deficit; if *BP* is flatter than *LM*, a reduction of the deficit results. Thus from the point of view of other countries, the imported inflation due to an expansionary fiscal policy in the originating country could be accompanied by a surplus or a deficit in the balance of payments.

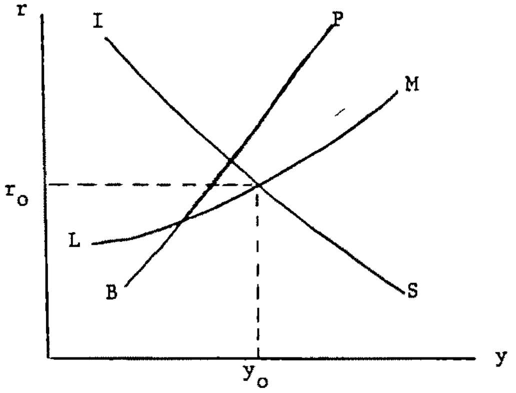

FIGURE 1: INTERNAL AND EXTERNAL BALANCE

The empirical results on the slope of the *BP* line generally tend to favor the case of relative capital immobility: *BP* steeper than *LM*. For example, my calculations (Branson 1975) using the S. Y. Kwack current account model and the Branson-R. D. Hill capital account equations for the United States show a *BP* line significantly steeper than *LM*. J. F. Helliwell reports simulations combining the MIT-Penn-SSRC (*MPS*) model of the United States and the Canadian *RDX2* model. These show a *BP* curve for Canada with about the same slope as *LM*; an expansionary fiscal policy in Canada is neutral with respect to the exchange rate or the balance of payments.

Thus it does appear that inflationary impulses emanating from shocks in the real demand sector in the United States are accompanied by *U.S.* deficits and surpluses in other countries, but only because of the relative immobility of capital in the

U.S. balance of payments. In general, the message of this simplest Keynesian model is that relationships between the balance of payments and the price level are complicated and not one-signed. If we know the source of an exogenous shock, we can probably determine what it will do both to the domestic price level and to the balance of payments. But knowing what it does to the balance of payments does not tell us what it does to the price level; we have to know the model and the source of the shock for that.

The Keynesian model described above is a pure flow-equilibrium model. It takes the stock of money as given, assuming that the authorities can sterilize the effects of the balance of payments on the money stock. That this is generally the case is suggested by the findings of Kouri-Porter and Herring-Marston, cited above. If we relax this assumption, and allow the foreign balance to affect the money stock, we come to the "monetary approach" to the balance of payments.

If an external imbalance is not sterilized, then as long as the *IS-LM* intersection is not on the *BP* line in Figure 1, the money stock will be changing, moving the *LM* curve, and moving the *IS-LM* intersection toward the *BP* line. If the internal balance point is below the *BP* line, there is a payments deficit, the money stock is shrinking, and the *LM* curve is shifting left, tending to reduce the deficit. The system comes to a stock equilibrium when the internal balance point lies on the *BP* line. This monetary approach is thus a simple extension of the bare-bones post-Keynesian model to adjustment of one stock—money—to equilibrium. The monetarist approach of section I is a further simplification, adding the small-country assumptions. It is only in that case that clear results for the transmission of inflation appear.

III. Convergence in a Keynesian-Phillips Model

One implication of the monetarist model is the convergence of national rates of inflation toward the world rate. One can obtain the same result from a Keynesian foreign trade multiplier model plus a price-Phillips curve, as well.

Begin with a price-Phillips curve,

$$\dot{P}/P = h(y), \qquad h_y > 0. \tag{7}$$

Here the rate of inflation is an increasing function of real output, given potential output. Next add a trade balance b = net exports, which is a decreasing function of the ratio of home to world prices:

$$b = b(P/P_w), \qquad b_p < 0. \tag{8}$$

Finally, holding constant real government spending and real assets, the foreign trade multiplier implicit in the Keynesian model can be summarized as

$$y = y(b), \qquad y_b > 0. \tag{9}$$

This completes the dynamic system. The trade balance depends on P, y depends on the trade balance, and y drives $\dot{P}/P$. Combining (7), (8) and (9), we have

$$\dot{P}/P = h(y(b(P/P_w))) = \lambda(P/P_w); \tag{10}$$

$$\lambda_p = \overset{+}{h_y}\cdot\overset{+}{y_b}\cdot\overset{-}{b_p} < 0,$$

as required for stability.

The system is described in the simple phase diagram of Figure 2. There the horizontal axis measures y and b in suitable units, and the rate of inflation $\dot{P}/P$ is on the vertical axis. First we locate the y^*, b^* values that yield $\dot{P}/P = \dot{P}_w/P_w$; these are equilibrium values. Then consider an initial point with y_0, $b_0 < y^*$, b^*. At that point $\dot{P}/P < \dot{P}_w/P_w$, so the trade balance is increasing, pulling up y and $\dot{P}/P$ toward the equilibrium point, as shown in Figure 2. If we began with y, $b > y^*$, b^*, we would see movement back

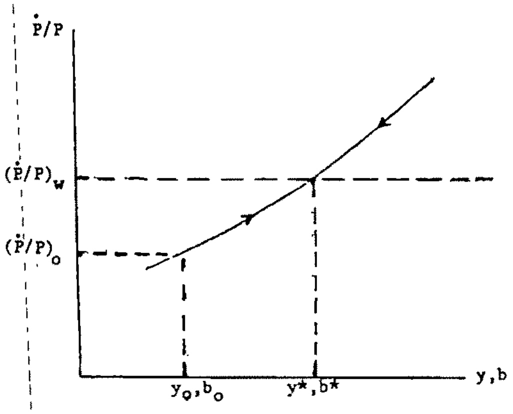

FIGURE 2: HOME RATE OF INFLATION CONVERGES ON THE WORLD RATE

down the phase line. Thus in the absence of policy action, the Keynesian-Phillips model would predict that national inflation rates would tend to converge toward the average world rate, through the action of the foreign trade multiplier.

This line of analysis yields two interesting implications. First, implicit in the Keynesian-Phillips view of inflation is a tendency (a) for rates of inflation to converge, and (b) for real output and unemployment rates to adjust so that rates of inflation converge. This happens through the foreign trade multiplier. Second, since inflation rates tend to converge on the Keynesian-Phillips view, evidence that they are converging, taken alone, cannot be used to support the monetarist view. Thus research designed to distinguish between Keynesian and monetarist adjustment mechanisms must go beyond the study of converging rates of inflation to model the actual mechanism behind such convergence, if it in fact occurs.

Understanding World Inflation

By GEORGE L. PERRY*

As the title of this session indicates, we economists are now grappling with the problem called "worldwide" inflation before having really understood "plain old" inflation. Complicating an unsolved problem is seldom a fruitful research strategy. Yet there is no avoiding the global scope of today's inflation and the connections between national economies that may contribute to it. Financial flows among nations complicate domestic monetary policies. Trade transmits the ebb and flow of aggregate demand from one nation to others. The prices of goods traded internationally move together. But such relationships could and have been deflationary as well as inflationary. The crucial questions are whether and why these relationships have been systematically inflationary to each country's price level; and more important, why the problem is inflation in the first place.

Today's inflation is complex, not simple; it has diverse causes, not a single cause; and it is rooted in institutional characteristics of economies that vary in important ways from country to country. It helps to sort some of the major economic developments of recent years into three aspects of the inflation process: its origin, its transmission, and its propagation. These categories are not analytically precise, but they do represent distinguishable parts of the process that has led to today's price performance in different countries.

Price increases have originated in several distinct ways. In the United States, domestic inflation originated in the late 1960's as excess aggregate demand led to overly tight labor markets and more rapid rates of wage and price increase. The food price explosion, which has been a large part of the 1973 and 1974 price increase story, resulted from a global imbalance of supply and demand that came from disappointing weather and wayward anchovies. The formation of an international cartel that quadrupled the world oil price is responsible for another large part of the observed increase in price levels since the fall of 1973. In late 1972, the coincident boom in industrial output around the world started other raw materials prices soaring. These are all very different initial sources of price increase. Yet all generated a part of what we call the inflation of recent years.

The transmission of economic developments across national boundaries takes place through several channels, including export demand, financial flows, and goods prices. There are obvious examples of each channel transmitting inflationary disturbances in recent years. The original price increases just identified directly meant higher prices for importing nations. The decline in the *U.S.* trade surplus, which eventually became a large deficit in the early 1970's, had its counterpart in rising exports from other nations. During this same period, a flood of *U.S.* dollars found its way to European capital markets.

According to the analytic categories I am describing, these transmissions are not the crucial step in the global spread of inflation. Whatever the origins of a price rise, or however inflationary tendencies are transmitted across national boundaries, the process would be limited if inflationary disturbances did not propagate further inflation. But in fact they have, and in a variety of ways, some reflecting structural characteristics of economies and some reflecting policy actions or inactions. In the United States, after having fallen behind average wage changes during the late 1960's, powerful unions caught up in the early 1970's, long after labor demand had eased. In most countries, rising export demand that accompanied the deterioration in the *U.S.* trade position was not offset by revaluation or more restrictive fiscal-monetary measures. Foreign monetary authorities did not neutralize the effect of dollar inflows to European countries and thus permitted them to result in a large expansion of domestic liquidity. Finally, in most countries, the food and fuel price explosions of recent quarters have apparently led to soaring wage increases, which have translated the food and fuel price increases into rising costs and prices for domestically produced output.

---

* The Brookings Institution.

Some would argue that all this describes symptoms of inflation rather than inflation itself, that it points out the places that get flooded while missing the fact that the dam broke. It is convenient to model the world economy by letting crop failures, cartels, and devaluations determine relative prices while the price level and inflation are determined by something simple like the money supply. But nobody should pretend that model answers any of the hard or interesting questions. Even if M_1 could tell us all we need to know about nominal incomes, knowing the growth of nominal income does not tell us how much of it would be real output and how much a rise in the price level. Surely the answer was different after the oil cartel formed than before. It was also different in 1960 from 1970. And what the possibilities are for 1975 is a source of considerable uncertainty, interest, and importance today. What we need to understand is why economies are inflation prone so that restrictive fiscal-monetary measures to combat inflation are so costly and unpopular.

In recent years, with only a few exceptions, countries have used neither fiscal-monetary restraint nor currency revaluation with enough force to hold down prices. It has been argued that European governments were powerless to mop up the excessive liquidity caused by dollar inflows, so they had insufficient control over nominal aggregate demand in their own countries. A refinement of this argument brings in the Eurodollar market and multinational firms as institutional impediments to the conduct of national aggregate demand policy. It has also been argued that currency revaluations are difficult owing to the political strength of export industries. Such assertions may contain some truth and may help explain some policy actions or inactions. But the inflationary bias in supply conditions of most economies and the tradeoff dilemma that this poses for aggregate demand policy are the more fundamental problem. If more fiscal-monetary restraint would have prevented inflation without a politically unacceptable cost in jobs and output, it is likely we would have seen more of it.

Several strands of thought have been developed in recent research on the inflation-unemployment tradeoff, most of them offering explanations for why the tradeoff has worsened. For the United States, it is now fairly well established that demographic shifts in the composition of the labor force mean labor markets are tighter today for any given aggregate unemployment rate. Women and younger workers of both sexes, on the average, enter and leave the work force more frequently than adult males and change jobs more frequently, encountering more spells of unemployment in the course of these transitions than workers with more permanent job attachments. In addition, some researchers have argued that the real cost of unemployment to workers has fallen as a result of more generous welfare and unemployment benefits, thus worsening the tradeoff by reducing the downward pressure that unemployment exerts on the average wage level. On my reading of the evidence for the *U.S.* economy, the first of these effects is noticeable in size, while the second is of uncertain importance. The same effects may have had much different importance in other countries.

Once allowance has been made for factors such as these that may have shifted the inflationary implications of any particular unemployment rate, several additional questions remain to be settled concerning the relation between inflation and labor markets. Much recent research has emphasized the importance of long lags in the inflation process as another explanation of why the short-run tradeoff has worsened. Excessive tightness in labor markets initially has a modest effect in speeding up wages; but with the passage of time, this effect is substantially magnified and wages end up rising much faster than current labor market conditions alone can explain. This kind of effect is often associated with the accelerationist literature, but it is also a part of many more general models of the labor market. It has been advanced both by economists with an atomistic view of the labor market and the way wages are determined and by economists who assign a major role to noncompetitive market power determination of wages. A lot of inflation modeling in the United States has worked with the competitive model, while Scandinavian and British economists have often stressed the importance of market power by labor unions.

Long lags have been hypothesized either through a wage-wage interaction or, more commonly, through a price-wage interaction. Whether a wage-wage or price-wage mechanism is at work is important: recently price indexes have accelerated everywhere for reasons unrelated to wage costs. Presumably we should have expected continued wage moderation on a wage-wage view of the world, but a sharp acceleration of wages on a price-wage view. This also raises another crucial distinction. If we believe a price-wage view, what is the relevant price? Is it the consumer price index which measures the real wage in terms of purchasing power of workers? Or is it a product price index, based on the output produced by labor, which measures the value of labor's marginal product? These distinctions are generally glossed over when lagged effects in the inflation process are simply attributed to expectations. Some sort of distributed lag can be fitted to almost any variable designed to measure wage or price increases and will give a tolerably good fit to the data without addressing any of the crucial structural questions about what actually determines the rate of wage increase.

Many of these unanswered issues about the generation of inflation are sharpened when we focus on the propagation of inflation. First, if the wage-wage model is appropriate, then rising prices of imported goods will not be propagated through faster wage increases into rising prices on domestic production. Alternatively, if the prices of goods labor produces matter in wage determination, then higher import prices could affect wages in the import-competing sector by raising prices in that industry. A further propagation of domestic inflation would then depend on whether a wage-wage mechanism existed that would extend the wage inflation to all of domestically produced output. Finally, if it is living costs that directly affect wages, then higher import prices would directly generate higher domestic wages and, hence, higher prices for domestic production.

Some of these issues can be viewed against the *U.S.* experience of the last couple of years, when sharp divergences among different price measures offer an unusual opportunity to discriminate among different views of the inflation-propagation process. Devaluation did appear to raise the price of Pintos and similar American car makes by raising the price of foreign small cars with which the Pinto competed. And, of course, prices of domestic oil and alternative energy sources rose with world oil prices. How much more of such a pricing response occurred is obscured by the fact that the pricing rules under Phase III of the Wage-Price Control Program were relaxed in 1973 and the fact that some *U.S.* industries, such as steel, were operating at or near capacity that year. Some part of nonfarm price increases during the past two years has come from these sources rather than directly in response to the higher price of competing imports. Nonfarm prices had fallen behind their historic relation to standard unit labor costs during Phases I and II of the wage-price program, and the restoration of precontrol margins, together with the continuing rise in standard unit labor costs, would have predicted about all of the 15 percent rise in average nonfarm, nonoil prices that has occurred in the two years through the third quarter of 1974.

If the main story in the recent *U.S.* price acceleration is food, fuel, and post-control catchup, the main story in *U.S.* wages is relative moderation and very little propagation of inflation through any price-wage-price spiral. Except in a few strong unions that established significant escalator clauses, wages have not responded to the consumer price increases of 1973 and 1974 in anything like the way an elasticity of 1.0 on living costs would have predicted. In fact, real compensation per manhour has actually declined in each of the last six quarters. Unless wage developments in 1975 reverse the verdict, this will be potent evidence against a strong price-wage mechanism working through living costs. Not only has the soaring price of food and fuel not been converted into correspondingly faster rates of wage increase, but even rising prices of nonfarm (nonoil) output have not thus far been translated into a corresponding acceleration of money wages.

The structural response of wages in other countries appears to have been substantially different from this. The striking acceleration of money wages elsewhere suggests either that their labor markets have been much tighter than those in the United States and, indeed, much tighter than in the past experience of most of these countries themselves, or else that the response of wages in some other countries to outside price increases is very different. I suspect the latter explanation is the more important part of the story. Over the most recent twelve- and twenty-four-month periods, it appears that average wages have risen faster than consumer prices in Great Britain, France, Germany, Japan, and Italy, although I must warn that I am uncertain about the reliability of the wage measures behind these calculations. If these measures are close to correct, these countries have a wage-determining structure that is much more closely indexed to consumer prices and more inflation prone than the process in the United States. Understanding the reasons for such differences would be an important step in understanding what makes economies inflation prone.

Governments are now going down the road of choking off aggregate demand to try to stop inflation. On the evidence, fiscal-monetary authorities are confronted with an impossible assignment in trying to maintain both prosperity and price stability in the face of substantial inflationary biases in their economies and inflationary shocks from abroad. Understanding inflation comes down to understanding these biases. And really curing inflation cannot mean simply causing enough unemployment to make it stop, but rather must involve reducing the biases and finding ways to make our institutions less inflation prone.

In the United States, fruitful research was being done in recent years aimed at understanding the kind of inflation where prices rose at an average rate 2.5 to 3 percent slower than wages. We were also experimenting with a wage-price program with some success. The price explosion that came from food and fuel made all that research and political effort that was aimed at the annoying first few points of inflation look rather trivial and impotent. But when the dust has settled, it is the kind of work we should get back to.

Monetary Growth and the Long-Run Rate of Inflation

By Richard T. Selden*

Arthur Okun invited me to join this panel, one presumes, to present a monetarist view of inflation. This I shall do. In my judgment the current worldwide inflation, like virtually all of its predecessors throughout history, stems from excessive expansion of the money supply. I believe that this could have been prevented, at least in the United States, without either loss of jobs in the long run or danger of financial collapse. The only hope of restoring reasonable price stability is to cut monetary growth to the rate of growth of full employment output and to hold it there indefinitely. Implementing such a policy will not be easy but it is our only hope.

Most recent literature on inflation suffers from two serious faults: it fails to examine the problem in a sufficiently long-term perspective and it takes inadequate account of delays between causal disturbances and inflationary consequences. On the first point, most writers on inflation are preoccupied with ephemeral symptoms or temporary disturbances. Events such as a rise in the minimum wage, a poor corn crop, the formation of an international oil cartel, devaluation of the dollar vis-à-vis other major currencies—the list could on and on—are capable of moving the inflation indicators upward, at least temporarily. However, such alleged causes of inflation operate only sporadically; they cannot explain a sustained rise in prices. One could write a history of inflation that would explain it as a series of unrelated accidents. As social scientists we should eschew such "ad hocery." One way of avoiding this trap is to focus on longer-term price movements rather than on month-to-month or quarter-to-quarter changes. I have concluded that the best time frame for the analysis of inflation is three- or four-year periods. Evidence of this sort is introduced below.

On the second point, the notion that there are long lags in the effects of policy measures is now widely accepted by economists, and even by some policymakers. Nevertheless, I believe that lags in the influence of monetary disturbances on the rate of inflation are much longer than most people believe them to be. For the United States they appear to be three years or more. If I have read the evidence correctly, the major determinant of price trends in 1973–74 is the monetary policies that were followed during the period 1968–71. By the same token, errors in monetary policy during 1971–74 will assure the continuation of rapid inflation into the year 1978.

I.

Let me briefly outline the sort of inflation model that I have in mind. First, I assume that the money supply is subject to close Federal Reserve control over periods of several months. Second, I hold that the monetary growth rate is the major determinant of growth in nominal income. However, this linkage does not work instantaneously. The immediate consequence of an acceleration of monetary growth is a decline in the velocity of circulation. Full recovery of velocity to its normal level requires from four to eight quarters, and accordingly price effects are muted during this adjustment period.

---

* University of Virginia.

Third, like many other economists, I assume that output responds to monetary disturbances faster than prices. The division of changes in nominal income between output and prices in the short run varies directly with the size of the income gap. Finally, I believe that monetary disturbances have no lasting impact on output; the entire effect is on prices.

There is nothing novel about such an inflation model. Broadly similar models have recently been presented by several economists, including Leonall C. Andersen and Denis S. Karnosky, Phillip Cagan, David Laidler, and Bennett T. McCallum. An essential feature is that the influence of money on prices will be spread over long time spans if the adjustments of income to money and of prices to income changes are protracted. Examination of *U.S.* data suggests strongly to me that both conditions hold.

But leaving econometric results aside, is it plausible that prices lag several years behind money? I believe that it is. The case has been stated far better than I can possibly do in these brief remarks in an excellent study by Cagan, *The Hydra-Headed Monster*. For a variety of reasons the impact of aggregate demand on prices works primarily through effects on costs, including notably wage costs. Many of these costs adjust only at infrequent intervals. They are probably influenced in many instances by price anticipations, which appear to be based partly on past price experience. And many prices are controlled or at least influenced by public regulatory bodies.

Given the fact (as I regard it) that the influence of demand on prices is spread over substantial time periods, it is not surprising that in a given quarter nonmonetary factors will dominate the less dramatic but more persistent monetary factor. It is fallacious, however, to infer from this that money does not matter as far as inflation is concerned.

II.

This is not the place to bring forth substantial empirical evidence in favor of the monetarist view of inflation. However, I hope I will be forgiven for introducing one table that summarizes some crude but suggestive evidence based on regressions of quarterly series of three- and four-year percent changes in prices and money. I call such changes the ***long-run*** rates of inflation and monetary growth. The results are displayed in Table 1.

For the United States during the period 1958–I to 1971–II I have found a strong association between money and prices even without lagging money, regardless of the money measure used. However, R^2 was maximized (at .86) when the money variable was lagged fourteen quarters. There was not much difference among the results obtained in the twelve- to fifteen-quarter lag cases. However, R^2 declined steadily as the lag was shortened and when leads were introduced. Addition of the long-run output growth rate—without leads or lags—as a secondary explanatory variable lifted R^2 to .91. The coefficient on output was negative, as expected.

After pondering these *U.S.* results I decided to look at other industrialized economies. Guided mainly by the ease with which reliable data could be put together, I regressed long-run inflation rates on monetary growth in Belgium, Canada, the Netherlands, and Sweden. The results were remarkably consistent with those for the United States. In each instance there was a close association between money and prices, and in each instance the best fit was obtained when the money variable was lagged two years or more. For all of these countries it was

TABLE 1—MONETARY GROWTH AND THE LONG-RUN RATE OF INFLATION, FIVE COUNTRIES

Country	Period	Variables	Lags (qtrs.)	Constant	Ind. Variables	R^2
United States	58-I—71-II	P, M (3-yr. % ch.)	14	0.01	1.04	.86
				(0.02)	(17.56)	
Belgium	58-I—70-IV	P, M (4-yr. % ch.)	8	− 0.02	0.47	.87
				(− 0.13)	(18.21)	
Canada	58-I—71-II	P, M (3-yr. % ch.)	8	0.70	0.23	.83
				(5.53)	(15.66)	
Netherlands	58-I—74-II	P, M (4-yr. % ch.)	8	0.28	0.52	.70
				(0.75)	(12.17)	
Sweden	58-I—71-IV	P, M (4-yr. % ch.)	15	2.53	0.24	.59
				(13.73)	(8.88)	

Notes: Figures in parentheses are t statistics. For the United States, P refers to the *GNP* deflator and M is M-1 (without seasonal adjustment). For other countries, P refers to the consumer price index and M to narrowly defined money.

necessary to work with changes over time spans of three or four years in order to get a proper appreciation of the role being played by money.

How can we explain the differences in R^2 among the countries included in the table? The Netherlands and Sweden, of course, pioneered in the use of incomes policies. Repeatedly they have adopted price freezes and wage restraint as means of coping with inflationary pressures. Even though these episodes of direct controls usually have not lasted very long, they have distorted the normal relationships between money and prices, thereby reducing R^2. In Belgium, Canada, and the United States, on the other hand, the impact of controls has been minimal, up to the early 1970's.

Why lags are longer in the equations for Sweden and the United States is not easy to explain. Both countries tend to follow three-year patterns in collective bargaining, in contrast to Belgium and the Netherlands; but so does Canada. The greater international exposure of Belgium and the Netherlands than of Sweden, and of Canada than the United States, may partly explain these differences.

III.

The behavior of the long-run inflation rate in the United States since mid-1971 is particularly instructive. The long upward march of inflation was halted abruptly after the second quarter of 1971. For the rest of 1971 and throughout 1972 the inflation rate fell quite sharply. On the other hand, the *expected* inflation rate on the basis of prior monetary growth continued to rise. By early 1973, when Phase II gave way to the more flexible Phase III, the discrepancy between actual and expected inflation was huge. The tight controls of Phase II probably would have disintegrated soon if the Nixon Administration had not ended them. 1973 has been called the year of infamy as far as price developments are concerned. Such dramatic language is beside the point. In my view, 1973 was simply a year of "snapback" to inflation levels that were consistent with previous monetary growth. While this adjustment was taking place, the short-run inflation rate soared far above the long-run steady-state rate of about 7 percent per year. Hence, we got double-digit inflation without ever having experienced double-digit monetary growth. But, of course, this hardly refutes the monetarist view.

By the third quarter of 1974, the snapback of prices had been completed. Although there may be some overshooting of actual long-run inflation rates above predicted rates for another quarter or two, I believe that a more likely outcome is a sudden drop of the actual long-run rate to the 6–8 percent per year zone. I expect this kind of a drop in the first half of 1975. However, the excessive monetary growth that has prevailed during much of 1971–74 almost ensures that President Ford's announced goal of whipping inflation by Independence Day, 1976, will not be even closely approximated. The equations in the table suggest that inflation will stay in the 6–8 percent per year range at least until the beginning of 1978. What happens after that depends on Federal Reserve policy in the months ahead. If we are to enjoy price stability in 1978, we must resist the temptation to administer massive monetary stimulation now.

IV.

To conclude these comments, I would like to consider briefly some objections. One frequent objection to monetarism is that it ignores the existence of very substantial reverse causality: monetary growth may be a function of the rate of inflation. My brief reply is that I am not at all persuaded by this criticism, given the long lags previously alluded to. A second objection is that insufficient attention has been paid to the *global* aspect of current inflation. This I regard as largely a consequence of inadequately flexible exchange rates—certainly prior to August 1971 and even since that fateful date. If the United States inflates and other countries tend to support the dollar, then these countries must expect to import inflation from us.

A third objection is more substantial. All of the equations in Table I (aside from the United States equation) underpredict the extent of inflation since 1971. This may reflect failure to measure money correctly through omission of Eurodollar balances. A more likely explanation is that the failure to include output as an explanatory variable is responsible. The sizable decline in those countries' incomes in the wake of the oil crisis may have exerted a significant one-time upward thrust on inflation rates.

Clearly a great deal more work must be done before we can be confident that we fully understand worldwide inflation. In the meantime, policy decisions must be made, for good or for ill. I cast my vote for continued monetary expansion in the 3–4 percent per year range, coupled with a modest tax cut and federal expenditure restraint. Such a policy will not work miracles but it has a good chance of restoring both price stability and full employment by 1978. In the present state of the art we cannot hope to do better.

Interpreting Recent World Inflation

By RONALD L. TEIGEN*

The measured price levels and money wage rates of most industrialized countries began to increase rather rapidly beginning about the mid-1960's, after having risen quite slowly for the previous decade or more. Evidence has been published indicating that the dispersion of individual country inflation rates about the across-country mean declined during this period. Findings along these lines for recent years are presented in the recent Organisation for Economic Co-Operation and Development (*OECD*) special report on the international transmission of inflation, for example. They are generally accepted as fact, probably because theory states that, in a world of trading under rigidly fixed exchange rates, individual country inflation rates must converge to a uniform world rate in the long run. Beginning from the premise that national inflation rates recently have been converging at a noticeable rate, it is perhaps a natural next step to try to identify the dominant causal force which is at work. For instance, the *OECD*, although claiming to hold an eclectic view, takes the position that convergence is due most immediately to the consequences of increasing economic interdependence among trading nations as exemplified, e.g., by the growth in the foreign sector relative to the domestic economy which has been characteristic of many countries. It assigns special importance to the direct effects of import and export prices on domestic costs and prices, suggesting in effect that a type of cost-push process is becoming increasingly important as the world trading system becomes more and more unified.

A popular alternative view, which does not depend on growing interdependence, is that the quickening and converging of national inflation rates are due to a rapid increase in world liquidity over the past few years, with both the accelerating expansion of domestic money supplies in the United States and elsewhere and the massive United States balance of payments deficits at the turn of the decade and into the 1970's being the primary driving forces, but with the introduction of Special Drawing Rights and the development of the Eurocurrency market also playing a significant role. Still others see such factors as demonstration effects, increasing labor militancy, or decisions by stabilization authorities to foster full employment rather than stable prices as the ***primum mobile***.

Whatever the particular viewpoint, the premise that inflation rates among countries are not only moving in the same direction but are noticeably converging toward a uniform rate undoubtedly has encouraged the tendency to identify one set of forces or another as primal. In what follows, I shall present some evidence which casts doubt on the proposition that national inflation rates have been converging in recent years. In doing so, it is not my intention to deny the theory that these rates eventually must converge in a fixed exchange rate world, nor do I reject the proposition that trading countries are becoming more interdependent. What I shall argue is that, since the evidence on convergence is mixed at best, it is preferable to interpret recent experience from an eclectic viewpoint, under which several different causal phenomena probably have been of some importance. As a first step, then, I want to present some evidence on movements in inflation rates and their dispersion.

---

* Professor of economics, University of Michigan.

The *OECD* evidence on convergence of national inflation rates in the special report mentioned above is summarized in a figure (*OECD*, Chart R, p. 82) in which the coefficients of variation of the *GNP* deflators for seventeen *OECD* countries, as well as for thirteen Northern European countries, are plotted annually over the period 1956–73. A trend line with a pronounced negative slope is fitted through these observations, and it indicates that, if past and current tendencies were to continue, the coefficient of variation for the *GNP* deflators of these countries would be zero by about 1982. This downward-sloping trend line is the basis for the *OECD*'s view that world inflation rates are converging.

In considering this evidence, it should be recalled that the coefficient of variation, being the ratio of the standard deviation to the mean, will decline either because of decreasing absolute dispersion or a rising mean. If a reduction over time in the coefficient of variation caused by a rising mean inflation rate and a constant dispersion of individual country rates is interpreted as signifying a convergence of these rates, it is implied that this dispersion, as measured by the standard deviation, should normally change proportionately to the mean. It is not clear why this would be expected in the case of national inflation rates, especially in a world in which exchange rate changes, exogenous capital movements, and other factors interfere with the adjustments which would occur under a hypothetical fixed exchange rate system. Therefore an absolute measure of dispersion such as the standard deviation may be more appropriate in this context than the coefficient of variation. In any case, there is some evidence that the dispersion of inflation rates may have begun to increase in recent years even when measured by the coefficient of variation. It is to this evidence that I now turn.

I have not been able to review the year-by-year experiences of all of the *OECD* countries. However, the data on compound growth rates of the consumer price index (*CPI*) and the *GNP* deflator which are calculated and published by the Federal Reserve Bank of St. Louis in its report entitled *Rates of Change in Economic Data for Ten Industrial Countries* are very convenient for my purpose. The countries included are Belgium, Canada, France, Germany, Italy, Japan, the Netherlands, Switzerland, the United Kingdom, and the United States; together they account for 84 percent of the imports and 85 percent of the exports of all *OECD* countries (as of 1971). I have calculated the means and standard deviations for the rates of change of the *CPI* and the *GNP* deflator over the three subperiods 1954–65, 1965–71, and 1971–73. The points of demarcation are somewhat arbitrary, but are meant to correspond roughly to the beginning of the acceleration of the Vietnam conflict (1965) and the breakdown of the fixed exchange rate system (1971). The results are reported in Table 1.

Both of these indexes record an acceleration in the rate of price increase after 1965 and a considerable further speedup following the breakdown of the Bretton Woods system in 1971. The numbers are slightly different, with the *GNP* deflator indicating higher growth rates than the *CPI*, but the patterns are the same. However, the patterns of dispersion for the two indexes are somewhat different, whether dispersion is measured by the standard deviation alone or by the coefficient of variation. Using the *CPI*, the standard deviation is constant for the first two subperiods and then increases during 1971–73. The coefficient of varia-

TABLE 1—MEAN ANNUALLY COMPOUNDED GROWTH RATES OF THE CONSUMER PRICE INDEX AND IMPLICIT GNP DEFLATOR, AND THEIR DISPERSIONS, FOR TEN INDUSTRIAL COUNTRIES, 1954–73[a]

	Consumer Price Index	Coefficient of Variation	Implicit GNP Deflator	Coefficient of Variation
1945–65	(In Percent)		(In Percent)	
Mean	2.7	0.33	3.3	0.27
Standard deviation	0.9		0.9	
1965–71				
Mean	4.3	0.21	4.7	0.13
Standard deviation	0.9		0.6	
1971–73				
Mean	7.0	0.16	7.1	0.18
Standard deviation	1.1		1.3

tion falls in the latter two subperiods compared to the first, due to the sharply increasing mean inflation rate. Using the implicit *GNP* deflator—the same index employed by the *OECD* in the aforementioned study—the standard deviation falls by one-third in 1965–71 while the mean rises by more than one-third; this results in a halving of the coefficient of variation. However, the standard deviation doubles in 1971–73 as compared with 1965–71. Even though the mean inflation rate also rises sharply in this subperiod, the coefficient of variation rises considerably as compared to 1965–71.

At least for these ten important industrial countries, then, the evidence suggests that national inflation rates are not clearly converging, but rather appear to have become more diffuse in recent years. While some divergence might be expected for 1971–73 due to structural changes in the world monetary system, it is not clear that national rates were converging even in earlier years. As noted above, this finding tends to weaken single-cause views of the world inflationary process. Other evidence, such as there is, also is unfavorable to this approach. For example, studying the experience of seven countries (six of which are included here) over the period 1955–71, W. D. Nordhaus found that neither simple monetarist nor simple Phillips curve explanations of wage and price changes were adequate.

If single causes cannot satisfactorily explain recent experience, we shall have to rely on more *ad hoc* combinations of forces, events, and institutions. In this spirit, let us first consider the period 1971–73. I believe that much of the observed acceleration of inflation rates in these years was due to two causes. One, which is difficult to quantify, is the increased freedom to pursue domestic goals made possible for trading countries by the collapse of the Bretton Woods system. The other is the food shortage and consequent sharp rise in food prices beginning in 1972–73 (the oil price increases of late 1973 probably are not reflected in these data). Among the ten countries studied here, the rate of *CPI* increase rose in 1972–73 compared to 1971–72 by 20 percent or more in nine countries and by 30 percent or more in five. In a world characterized by downward price inflexibility, and in which high employment is an important goal, it is likely that the relative prices of other goods were lowered in response to the food shortage, and employment supported by accommodative policy and the acceptance of higher inflation rates.

Similar considerations probably apply to many countries in the period prior to 1971. Stabilization authorities have become more knowledgeable in managing demand, and at the same time, maintaining a high level of activity has become relatively more important as a policy goal. As a consequence, industrialized countries are operating closer to full employment more of the time than previously. This suggests both the acceptance of a higher average inflation rate and less possibility for error on the expansionary side without inflationary repercussions.

The other set of factors whose importance I want to emphasize is monetary in nature. Although I do not agree with the monetarist view that increases in world liquidity are both necessary and sufficient to generate a rising rate of world inflation, I certainly believe that such increases have in fact played an important role in recent years. Among the ten countries examined, the unweighted annual average compound growth rate of their money supplies was 8.0 percent in 1954–65, 9.6 percent in 1965–71, and 13.7 percent in 1971–73. Certainly this must have been expansionary; the problem lies in determining what part of this growth represented policy initiatives and what part was accommodative in the sense of a policy response to external conditions, designed to maintain employment or defend some other goal.

Whatever their origin, monetary impulses propagated through the trading world by balance of payment changes can create special problems for countries with underdeveloped financial markets and institutions in which it is difficult for the authorities to neutralize the effects of such changes on the domestic monetary base. Open market operations typically cannot be used in such economies, and other devices such as reserve requirement changes have their own substantial limitations. Consequently, capital flows tend to have immediate and substantial repercussions on domestic liquidity. Those originating in the United States balance of payment deficits in the pre–1971 period must have resulted in substantial increases in liquidity, and consequently in expansion and in upward pressure on prices, in many of these countries.

DOMESTIC ADJUSTMENT TO BALANCE OF PAYMENTS DISEQUILIBRIUM

The Payments Adjustment Process and the Exchange Rate Regime: What Have We Learned?

By MARINA v. N. WHITMAN*

In taking stock of what we have learned about domestic adjustment to exchange rate change since the end of the Bretton Woods system, the first step is to try and define the nature of the exchange rate regime we are talking about. Certainly, the exchange rate situation of the past few years is a far cry from the system of freely flexible rates so beloved of textbook writers. Rather, it is a state of transition, without clearly defined rules of behavior, characterized by "probably the widest combination of exchange systems ever with the exception perhaps of the mid-1930's." As of mid–1973, an official of the International Monetary Fund (*IMF*) noted:[1]

> that at present we have 10 countries floating with different degrees of intervention; we have 8 countries floating as a bloc, maintaining a very close relationship among themselves but with no obligation whatsoever to defend a rate with respect to the dollar; and we have 24 countries that have pegged their currencies with respect to the dollar; 14 with respect to the French franc; and 11 with respect to the pound; and we have 53 other countries that have either declared central rates or par values which they defend by intervening in any of the three above-mentioned currencies. [p. 107]

I. The Nature of the Present System

As this brief summary suggests, the present situation is one characterized by active and to a considerable extent uncoordinated behavior on the part of national central banks. Many countries behave as though they have explicit current account targets, and therefore implicit exchange rate targets, rather than being willing to allow exchange rates to move freely to clear the foreign exchange markets. The present lack of coordination is evidenced not by the direct intervention of countries in the foreign exchange markets, regarding which there has apparently been considerable consultation, but rather by what might be termed their indirect intervention: central bank or government activities which not only have a significant impact on the foreign exchange markets but which are undertaken for the primary purpose of modifying or restricting the behavior of those markets.

One form of indirect intervention by which countries may seek to avoid or reduce reserve losses or, alternatively, depreciation of their currencies is by foreign (as opposed to domestic) borrowing by governmental or government-related authorities. France, Italy, the United Kingdom, and Japan were among a substantial number of countries which utilized large-scale foreign borrowing by public-sector institutions, particularly in the Eurodollar market, to strengthen their payments positions late in 1973 and early in 1974.

[1] Statement of Ricardo H. Arriazu, Alternative Executive Director, *IMF*, in U.S. Congress (93–1) p. 107. See also, Council of Economic Advisers, Table 53, p. 197.

The most common and time-honored method of modifying exchange rate or reserve positions is, of course, some form of direct control over international transactions. The period since August 15, 1971 has witnessed a widespread escalation of controls for balance of payments purposes, imposed primarily by surplus countries to limit capital inflows and thus prevent or, more often, hold down the appreciation of their currencies. The fact that such controls were relatively ineffective in stemming the tide of mobile funds did not prevent the surplus countries from applying them with progressive tightness and in increasingly diverse forms.

Even after the move to a system of what was termed "generalized floating" early in 1973, the use of direct restrictions to modify external positions continued.[2] The widespread relaxation of import restrictions and the imposition of taxes or limitations on exports during 1973 were, with a few exceptions, directed at the alleviation of domestic scarcities and inflationary pressures rather than at external targets. But toward the end of that year, following the sudden developments affecting the price and availability of petroleum imports, this trend among the developed countries toward liberalization of import restrictions tapered off. In a few countries with severe payments problems the liberalizing moves were in fact reversed; the most dramatic example of this was the imposition by Italy in May 1974 of a 50 percent deposit requirement on imports, including imports from its partner countries in the Common Market.

Despite a few such widely noted exceptions, direct controls for balance of payments or exchange rate purposes have continued to be focused primarily on the capital rather than the current account. Efforts to curb capital inflows were stepped up in many industrialized countries early in 1973, often accompanied by measures to liberalize capital outflows. But by the latter part of 1973, after the advent of the petroleum problems, many developed countries moved to liberalize capital inflows and, in a few cases, even reimposed curbs on capital outflows. There was one major exception: the United States programs to restrict capital exports had been liberalized in 1973 and, in January 1974, encouraged by the substantial strengthening of the dollar over the previous six months and by the safety valve against speculative disasters provided by floating rates, the *U.S.* government abolished all three of these programs. Nonetheless, despite some major exceptions, the early experience with greater flexibility of exchange rates suggests that, contrary to a priori expectations, it has been accompanied by an increased reliance on direct controls aimed at the modification of countries' external positions.

The "floating rate" system of the recent past has clearly been heavily managed, by both direct and indirect intervention; it has also been characterized by substantial fluctuations in exchange rates. In the eighteen months following the Smithsonian Agreement, the trade-weighted effective exchange rate of the dollar against thirteen major currencies fell by some 12 percent; in the next six months it rose again by an almost equal percentage and then fell again by some eight percentage points between January and May of 1974, to a level nearly 20 percent below pre-June 1970 parities, before rising again some five percentage points or so (Morgan Guaranty Trust Co.). Several other major countries experienced even larger changes in their effective rates of exchange (in May 1974 Germany's effective rate was 22 percent above and Italy's 25 percent below their respective pre-June 1970 parities) and fluctuations in certain important bilateral rates (such as the dollar-mark and dollar-yen rates) were larger still. Movements of several percentage points in the dollar-mark rate took place within a single week—occasionally, even within a single day.

---

[2] For surveys of payments restrictions in 1973, see Council of Economic Advisers, Table 54, pp. 198–99; International Monetary Fund *Annual Report*, pp. 44–46; and International Monetary Fund *Survey*, Sept. 2, 1974, pp. 274–76.

In a period characterized by sudden, dramatic changes in economic conditions affecting countries' external positions and by high and widely divergent rates of inflation, it is perhaps not surprising that movements in exchange rates were large, sharp and, on occasion, dramatically reversed. Nonetheless, these fluctuations do appear to have been somewhat larger than required for the elimination of latent flow disequilibria—balance of payments disequilibria in the usual sense. Some scholars have taken this as evidence that the exchange markets are inherently unstable. (See, for example, C. P. Kindleberger.) Others see it, however, as a transitional phenomenon, a temporary divergence between stock equilibrium and flow equilibrium resulting from a prolonged period of flow disequilibrium (as, for example, W. S. Salant). In this view, once the inherited dollar overhang is liquidated and the desired shift in the composition of reserve assets, both official and private, is completed, a major cause of the volatility in the valuation of the dollar vis-à-vis other currencies should disappear.[3]

II. Exchange Rate Change and the Stability of Foreign Exchange Markets

The fundamental question to which we seek answer from recent experience is, of course, whether greater flexibility of exchange rates is indeed an effective means of reducing or eliminating payments disequilibrium, thus alleviating the burden of adjustment which must otherwise be borne either by internal measures or by direct restrictions on international transactions. Because of limitations of time and space, I shall focus here on the experience of the United States, asking whether the effective devaluation of the *U.S.* dollar since mid-August 1971 has or has not served to reduce the deficit in the *U.S.* payments balance.

One difficulty with discussing adjustment to balance of payments disequilibria in the framework of a hybrid system of "managed floating"—in which disequilibrium is dealt with partly by exchange rate changes and partly by reserve changes—is that the system no longer always gives unambiguous signals indicating which side of equilibrium we are on. In such a situation, when at any given moment some countries are likely to be intervening in the exchange markets and others are not, it is possible for the dollar to be depreciating at the same time that the United States has an official settlements surplus, or vice versa. Although it is still generally possible to garner consensus views regarding a country's underlying external position, data on payments positions and changes in reserve balances no longer serve as unambiguous indicators in this regard.

Whereas during 1972 and the early part of 1973 the prevailing mood with respect to the *U.S.* balance of payments was one of elasticity pessimism (as evidenced by the further depreciation of the dollar in exchange markets following the official devaluation of February 1973), during the course of 1973 the tide began to turn, and the conviction grew that the Smithsonian devaluation was indeed having a favorable impact on the external position of the United States. Such systematic econometric evidence as is beginning to be available tends to confirm the conclusions derived from more casual empiricism, that the effective depreciation of the dollar has indeed been "successful."[4]

---

[3] Indeed, the demand for dollars to make oil payments appears already to have reduced substantially the magnitude of the "dollar overhang" problem in the eyes of other industrialized countries.

The econometric evidence available so far is scanty, piecemeal, and far from definitive. In particular, the studies which have been completed so far suffer from three major weaknesses as predictors of the impact of recent changes in the effective exchange rate of the dollar. First, they are carried out within the partial equilibrium framework of the elasticities approach, explicitly ignoring the induced effects of devaluation on domestic and foreign incomes and price levels. Such *ceteris paribus* estimates must be regarded as upper bounds for the *mutatis mutandis* effects of depreciation. Second, these studies encompass the effects on the merchandise trade balance only; virtually no econometric analysis of the impact on other elements of the current account or the long-term capital account is yet available. (An exception is S. Y. Kwack, 1974b.) Finally, these studies are also partial in the sense that the values of the underlying price elasticities for various components of exports and imports are assumed rather than estimated directly. That is, they utilize some combination of a priori reasoning and estimates derived from preexistent econometric studies to generate either point estimates or range estimates of price elasticities on which to base the analysis of the impact of depreciation on the *U.S.* trade balance. To my knowledge, no analysis of the 1971–73 period has generated its component estimates of price elasticities from scratch.

Given these inherent limitations, it is nonetheless encouraging that the various studies (W. Branson, P. B. Clark, and Kwack 1974b) are in broad agreement in concluding that a substantial improvement in the *U.S.* trade balance had already taken place by the end of 1973 as a result of the dollar depreciation, and that an even larger total improvement could be expected ultimately to result.[5] The various studies vary substantially in their estimates of the magnitude of the depreciation effect and they are noncomparable in many ways, including the models employed, the time periods of both observation and prediction, and whether or not the analysis related to the Smithsonian devaluation alone or to the total change in the effective exchange rate of the dollar over the 1971–73 period. Nonetheless, all generate estimates of a total favorable impact on the *U.S.* trade balance of several billions of dollars, although no estimate is as large as Secretary of the Treasury John Connally's original target of a $13 billion improvement in the merchandise trade balance.

The various studies of the impact of dollar depreciation on the *U.S.* trade balance differ in their estimates not only of the magnitude of the effect, but also of its timing. Estimates of the lag in the response vary from relatively short—implying that more than 50 percent of the total effect on export and import quantities takes place within one year (Kwack 1974b)—to rather long—suggesting that more than three years are required for half of the ultimate impact to have occurred (H. B. Junz and R. R. Rhomberg). But, despite these differences, the studies tend in general to confirm empirically the existence of a phenomenon which had been increasingly anticipated on a priori grounds,[6] the so-called J-curve effect.[7] The term J-curve refers to the existence of a nontrivial period of time during which the negative price effects of a depreciation dominate the positive quantity effects, implying that the initial effects of an exchange rate change on the balance of trade are perverse even when the elasticity conditions for long-run stability are satisfied.

---

[4] R. I. McKinnon (pp. 24–26) cites an econometric analysis of the impact of exchange rate change in six leading industrialized countries over the period 1968–74 to support his view that, from this broader perspective, the results are mixed. The study referred to is Wolfgang Kasper's.

[5] These are obviously *ceteris paribus* predictions, which leave out of account the substantial deterioration in the 1974 trade balance stemming from the fourfold increase in petroleum prices.

As regards the other components of the *U.S.* basic balance—the current account items other than merchandise trade and long-term capital flows—very little empirical analysis is yet available for the 1971–73 period. In terms of raw annual data, a steady improvement in the balance on long-term private capital flows from 1971 through 1973 is evident, without the dip in 1972 which characterizes the merchandise trade and current account positions. There are two reasons why one might expect a priori that a change in the exchange rate (as distinguished from the expectation of a future change in the exchange rate) will affect the net flow of long-term capital relatively quickly. One is the termination or reversal after a devaluation of capital outflows which had taken place previously in anticipation of that devaluation, a phenomenon which one would expect to be more significant under a system of adjustable pegs than in situations characterized by widespread floating. The second is the so-called portfolio-rebalancing effect, which arises from the assumption of portfolio theory that investors want to hold a particular optimum mix of assets in their portfolios and will attempt to maintain these proportions, denominated in their own domestic currencies, in the face of valuation changes arising from exchange rate changes. (See D. E. Logue and T. D. Willett.) Over the longer run, the improved competitive position of domestic export- and import-competing industries resulting from depreciation can be expected to attract increased investment from abroad.

Although empirical evidence regarding the role of these various effects in the recent period is as yet lacking, it seems on a priori grounds that, unless the portfolio-rebalancing effect is significant, changes in long-term capital flows, which are largely nonspeculative in origin, are likely to take place only gradually and with a significant lag following an exchange rate change. If this is so, it raises a question about the dynamic stability of foreign exchange markets in a world where markets clear rapidly and in which the initial response of the trade balance to exchange rate changes may be perverse (A. J. C. Britton). Actually, the question is a double one: Are exchange markets stable in the absence of government intervention and, if so, what makes them so?

Despite substantial fluctuations, the exchange markets for the dollar and other major currencies do appear to have been dynamically, though cyclically, stable in the period since mid-1971. That is, although fluctuations in rates may well have been larger than would have been required to eliminate underlying disequilibria, the major rate movements appear to have been in the "right" direction, that is, appropriate to actual or anticipated changes in basic economic conditions. Certainly rates did not appear to be in danger of shooting off toward zero or infinity. Nor could government intervention account fully for the existence of dynamic stability; such intervention, although substantial, has not been continuous or systematic enough to explain market behavior.[8] Rather, it would appear that private speculation, although inadequate in magnitude and speed of response, has indeed performed its traditional function of being stabilizing in the broad, despite widespread concern about "bandwagon" behavior unrelated to fundamental economic conditions.

---

[6] See S. P. Magee for a systematic discussion of the conditions required for a J-curve to exist.

[7] Again, Kwack (1974b) is an exception.

A pattern of speculative behavior which magnifies the amplitude of currency swings, requiring price changes which overshoot equilibrium in order to call forth equilibrating movements of funds, appears to be due to a paucity of continuous stabilizing speculation, resulting in the market thinness just described.[9] Although, again, the evidence at this stage is primarily anecdotal, there seems to be a widespread feeling that, despite a few widely publicized examples to the contrary, large *U.S.* banks have become increasingly cautious about assuming net positions in foreign currencies, either spot or forward. Even more marked is an apparent tendency for multinational corporations to overhedge against foreign exchange risk, owing in part to the current uncertainty among accountants as to the correct method for analyzing "translation costs," the changes in the domestic-currency valuation of foreign assets and liabilities resulting from a change in the exchange rate between the currency of the parent country and that of the country in which a subsidiary is domiciled.

Behavior of the sort just described is what one might expect during a learning period, when speculators' views regarding long-run equilibrium values are weakly held and substantial stimulus is therefore required to make them act on them. Certainly such learning behavior is consistent with the cyclical stability which appears to have characterized foreign exchange markets since the demise of Bretton Woods. However, much more systematic analysis of the behavior of exchange markets during this period, and of the roles played respectively by private speculation and by central bank intervention, is urgently required. Furthermore, sufficient time must elapse and the exchange rate system must settle down sufficiently to permit a distinction between temporary behavior associated with rapid transition and the more permanent behavior patterns associated with the new exchange rate regime before views regarding market stability can be held with reasonable certainty.

III. Feedbacks to the Domestic Price Level

The empirical analysis cited so far has focused primarily on changes in relative prices, abstracting from induced changes in domestic and foreign incomes and price levels. But there is a growing school of thought which holds that such analysis is fundamentally irrelevant; that the primary impact of exchange rate change on the balance of payments comes not through changes in relative prices of commodities, but rather through the direct effects on expenditure of the resulting change in the real value of money balances. An improvement in the balance of payments of a depreciating country, according to this "global monetarist" view, is a transitory phenomenon, stemming from the reduction in the real value of domestic cash balances as a result of the price increases associated with depreciation.[10] This fall in real money balances, if it is not offset by the monetary authorities, produces an excess demand for money and thus a temporary drop in expenditure relative to income. But, once domestic residents have built their real cash balances back up to the desired level through an increased payments surplus (or reduced deficit), the balance of payments will revert to its previous level. A further implication of this view is that any initial change in relative prices stemming from an exchange rate change will ultimately be offset by a combined increase in the price level of the depreciating country and decrease in the price level of the appreciating country.[11]

---

[8] R. A. Debs (p. 87) notes that official intervention in exchange markets between March 1973 and March 1974 exceeded $35 billion; my own rough calculations based on monthly changes in reserves suggest that intervention by G-10 countries totalled more than $35 billion during the calendar year 1973 and about $60 billion between the end of 1972 and October 1974. J. Williamson concludes from his statistical analysis of the experience of twenty countries that reserve use may actually have increased, and certainly has not decreased, under flexible as compared with fixed rates.

[9] McKinnon (pp. 17–21) also concludes that stabilizing speculation was lacking in 1973–74, and suggests that "the decline in the United States dollar as stable international money" may be a major reason for its paucity.

The controversy generated by this approach is less over whether the balance of payments effects of exchange rate change are transitory than over how long the transitory period is. The fact that, over long periods of time (e.g., decades), changes in exchange rates tend to offset—or be offset by—changes in relative price levels has long been recognized in the form of the Purchasing Power Parity concept.[12] The question at issue is whether this process of adjustment actually takes place relatively quickly. The global monetarist view is that high elasticities of substitution prevail among countries for most tradeable goods and that, because world markets are today highly integrated, a single price must prevail in all markets for goods which are close substitutes for one another.[13] The implication of this view is that competitive forces will quickly eliminate changes in relative prices stemming from exchange rate changes by offsetting changes in domestic prices.

No full-fledged econometric analysis of the balance of payments impact of recent exchange rate changes which utilizes the macroeconomic approach of the global monetarists has yet come to my attention. However, some empirical work has been focused on one hypothesis closely associated with this approach: the close-substitutes hypothesis.

While some of the empirical investigations of the effect of exchange rate changes on trade balances, discussed earlier, simply assume that certain categories of goods moving in world trade (chiefly primary commodities) conform to the close-substitutes model while other categories (mainly manufactured goods) do not, other studies attempt to evaluate the close-substitutes hypothesis directly. In general, the conclusion is that, at least for manufactured goods, the close-substitutes hypothesis fails to hold for the periods examined and at the levels of aggregation employed; that, in other words, "the relative dollar prices of industrial outputs do seem to change substantially and permanently (over the six-year period

---

[10] Examples of this approach are R. Dornbusch, H. G. Johnson (1969, 1972a, and 1972b) and A. B. Laffer. Whereas the elasticities approach deals with the impact of exchange rate change on the balance of *trade*, the global monetarist approach focuses on the impact on the balance of *payments*.

[11] Kasper concludes that "the evidence suggests that exchange rate changes had a more immediate and more substantial impact on export and import prices than on export and import volumes . . . the dominant impact of exchange rate changes on the prices of foreign trade would also suggest that the exchange rate instrument be assigned to the (domestic) price-level objective, especially in countries with open economies."

[12] See H. J. Gailliot, Laffer, and the references there cited. This may not be true in the short run, however. McKinnon (p. 29) notes that the sharp appreciations of European currencies against the dollar in 1971 and 1973 "seem completely inexplicable to a theorist relying on some notion of purchasing power parity. . . . Changes in exchange rates in 1973 and 1974 cannot be interpreted as better aligning national price levels."

[13] Johnson (1972b, pp. 1560–1561) notes that this close-substitutes model is a common but not an essential assumption of the global monetarist approach.

1968–73) when exchange rates change" (P. Isard, p. 17). Kwack (1974a) estimates that, on the average, a one percentage point devaluation would improve the relative price advantage of the United States by 0.7 percent (with *U.S.* prices rising in the long run by about 0.2 percent and foreign prices falling by about 0.1 percent.) J. R. Artus, looking only at the prices of manufactured exports, estimates that in the United States domestic price changes will ultimately (within two years) offset about 10 percent of an exchange rate change, while for four other major industrialized countries the proportion is likely to be between 30 and 40 percent. Combining these estimates implies, again, that the United States can expect to retain for some time more than half of a change in the effective exchange rate in the form of a relative price advantage for manufactured exports.

The close-substitutes model differs from the conventional view also in its implications regarding the effect of an exchange rate change on the domestic price level or rate of inflation. Under the assumptions of the conventional Keynesian model, that wages and prices are stable in terms of the home currency up to the point of full employment, depreciation of the exchange rate in the presence of unemployment would affect the domestic price level only via the increased prices of imports. Under these assumptions, the ratio of imports to *GNP* would set an upper limit to the impact of an exchange depreciation on the domestic price level. For the United States, whose imports constitute some 7.5 percent of *GNP*, an effective dollar depreciation of 10 percent could not increase the price level, as measured by the *GNP* deflator, by more than three-fourths of 1 percent (this represents an upper bound; because of the relative importance of the United States in world markets, it is most unlikely that the full amount of the depreciation would be passed through in the form of increased dollar prices of imports.) (See Isard, p. 3.) Under the assumptions of the perfectly competitive model, on the other hand, with elasticities of substitution between foreign and domestic goods approaching infinity, the upper bound on the increase in the domestic price level would be the amount of the effective depreciation itself. Actually, because the United States is far too large to be a price-taker in world markets, the dollar depreciation would be divided in some proportion between a rise in price level in the United States and a fall in the price levels of those countries whose currencies appreciated vis-à-vis the dollar.[14]

Although systematic evidence concerning the impact of the dollar depreciation on the acceleration of inflation in the United States is still scarce, two early studies which incorporate at least some of the indirect effects of depreciation on the domestic price level implied by the close-substitutes model have yielded reasonably consistent results. Utilizing regression results based on Phillips curve equations which incorporate an import-price term for the United States and "the rest of the world" over the period 1959–71, Kwack (1974a) estimates that, on the average, the *U.S.* price level as measured by the consumer price index would rise by about 20 percent of the effective depreciation of the dollar, or by two percentage points in the case of an effective devaluation of 10 percent. W. Nordhaus and J. Shoven, who use an input-output approach to estimate the transmission of the price effects of depreciation from the "exogenous" sectors corresponding to the close-substitutes model to the "endogenous" or sheltered sectors of the economy, conclude that the 10 percent effective devaluation of the dollar between November 1972 and August 1973 accounted for between one-fifth and one-sixth of the *U.S.* inflation, as measured by their adjusted wholesale price index, over the same period. Since inflation over that period, in terms of their index, amounted to 11.3 percent, and since their index appears to be closer in concept to the consumer price index than to the wholesale price index as actually measured, their attribution of between 1.9 and 2.3 percentage points of inflation to the effective depreciation of the dollar neatly brackets Kwack's partially a priori estimate of 2 percentage points.

---

[14] J. Salop notes that "the monetary approach most commonly appears as a small country model," in which the domestic price level rises by the full amount of an effective depreciation.

Although the studies just described yield far larger estimates of the impact of depreciation in the domestic price level than did the very crude *ex ante* calculations cited earlier, there is reason to believe that they may still underestimate this impact, by failing to take account of significant indirect effects on prices in industries producing exportable and import-competing goods and, through effects on rates of wage increase, on prices in nontradeable sectors as well. In particular, the improvement in our net balance on goods and services, in real terms, from a deficit of $0.8 billion in the fourth quarter of 1972 to a surplus of $11.6 billion in the fourth quarter of 1973 (in 1958 dollars) represented 38 percent of the total increase in real *U.S. GNP* over the period. At a time when many parts of the economy were clearly straining against capacity limitations (a pressure apparently not fully reflected in the rate of unemployment), the diversion of nearly 40 percent of the increase in real output from domestic to foreign absorption cannot help but have had effects on the domestic price level far more complex and pervasive than those captured in either of the models just described. In reality, as Johnson (1969) has suggested, neither the conventional closed economy model nor the fully integrated model of the monetarists is a realistic one; what is needed is a model which specifies differing degrees of imperfect substitution between domestic and foreign output in different sectors of the economy.[15] Although the studies just described make some significant steps in that direction, the full specification of a disaggregated model of imperfect substitution appears to be still some way off.

IV. The Exchange Rate Regime and World Inflation

The existence of a positive relationship between the depreciation of the dollar and the acceleration of domestic inflation in the United States is beyond dispute; the only questions relate to its magnitude. The relationship between changes in the exchange rate regime since mid-1971 and the dramatic increase in the *world* rate of inflation over the same period is, however, much less clear. Obviously, changes in exchange rates can be expected to push inflation around geographically, accelerating it in depreciating countries and retarding it in appreciating countries. But in formal terms these effects should be symmetrical, canceling each other out and leaving the world rate of inflation unchanged. Any net effect of exchange rate changes on the rate of inflation in the world as a whole requires asymmetries in either market or policy responses.

That such asymmetries should exist is not surprising; clearly there are differences among countries in their elasticities of supply and demand, in other structural characteristics of their economies, and in the responses of their policymakers. The problem is simply that it is by no means clear in which direction these asymmetries operate and, therefore, what the relationship is on balance between different exchange rate regimes and the world rate of inflation. Proponents of fixed rates, on the one hand, argue that a move to flexibility destroys balance of payments discipline as an external constraint on governments' inflationary policies, that the increased uncertainty associated with flexible rates creates an inflationary "flight from money," and that, if wages and prices are inflexible downward and factor mobility is imperfect, the excessive fluctuations or "overshooting" frequently associated with freely flexible rates will have an inflationary ratchet effect on the domestic price level, as well as moving the country's Phillips curve outward in an unfavorable direction.[16] Supporters of flexible rates, on the other hand, note: that in a world of downward inflexibility, the failure of deficit countries to deflate forces surplus countries to inflate against their wills; that the international liquidity creation associated with prolonged payments disequilibrium is bound to be inflationary; and that the large speculative capital flows generated by disequilibrium rates under constant pressure are on balance inflationary, particularly when they flow out of the reserve-center country as ordinary money and into other countries as high-powered money.

---

[15] R. J. Gordon notes that the close-substitutes monetary model is appropriate to the long run, while the closed-economy Phillips-curve approach is applicable to short-run policy analysis.

Despite considerable uncertainty regarding the nature of the asymmetries which govern the relationship between the exchange rate regime and the magnitude of world inflation, there is a persuasive case to be made that the Bretton Woods system, particularly in its final years, represented a particularly inflationary organization of the international monetary system. The four major elements of a one-sided adjustment process, a parity system based on a structurally weakening dollar, destabilizing capital flows, and uncontrolled expansion of international liquidity combined to produce a highly inflationary mixture in which neither the United States nor the other industrialized countries, taken together, felt external constraints on domestic inflationary pressures. (See Johnson 1969 and Emminger.)

At present, the international transmission of inflation is a painful phenomenon in search of a theory; "we have no general coherent theory of world inflation fully applicable to the present world monetary environment characterized by extensive floating" (G. Haberler, p. 4). Nonetheless, recent experience has made at least a few points clear. First, because of systematic differences between the United States and other countries in the relationship between the behavior of tradeable goods prices and that of more generally utilized indices like the consumer price index or the *GNP* deflator, it was possible for the United States to export inflation even when its own rate of inflation was very moderate and below that of other industrialized countries. Second, domestic credit creation may precede or preclude an inflow of reserves in a potential surplus country; such a reserve inflow is a sufficient but not a necessary condition of imported inflation (Johnson 1973 and Emminger).

The twilight years of the Bretton Woods system created widespread awareness that, without exchange rate flexibility, countries other than the key-currency country can exercise little control over their domestic money supplies and price levels. The promise of greater autonomy for domestic monetary policy has been one of the major arguments in favor of greater flexibility of exchange rates. However, the post-Bretton

---

[16] Kindleberger argues that floating rates add to structural inflation in some periods (as at present) and to structural deflation in others (as in 1929–32).

Woods experience has made it clear that the monetary autonomy made possible by flexibility of exchange rates has definite limits. First of all, such monetary autonomy requires not simply *flexibility* of exchange rates but *uncertainty* regarding the future course of exchange rates—uncertainty which at the same time threatens the continued growth of international trade and investment and, many fear, will eventually lead to the fragmentation of world markets. A moving exchange rate, such as a crawling peg, whose future values are known with certainty, allows no more room for monetary independence than does a fixed rate, although it alters the particular configuration of monetary policies that is consistent with the exchange rate regime. Second, while rate flexibility endows a country with greater control over the nominal money supply, to the extent that there are feedbacks from changes in the exchange rate to the domestic price level, the real money supply remains an endogenous variable rather than a policy variable subject to the control of the domestic monetary authorities.

The move to widespread rate flexibility has not provided complete autonomy for national policies in pursuit of domestic economic goals; neither has it abolished problems associated with the supply of international liquidity, either on the world or the individual country level. Because exchange rates are heavily managed, with considerable intervention in foreign exchange markets, one would hardly expect the demand for international reserves to drop to zero. At the same time, it is surprising that, in the words of the 1974 *Annual Report of the IMF* (p. 39), "there is not as yet any statistical evidence of a reduction in the utilization of reserves by countries that have allowed their currencies to float." The shift to widespread floating appears to have halted the explosive growth of world reserves which occurred in 1970–72 without clearly increasing, as one might have expected, the redundancy of the existing reserve stock by reducing the utilization of reserves.

Finally, while the change in the exchange rate regime failed to provide complete autonomy for national economic policies, neither has it spawned a rash of beggar-my-neighbor exchange rate policies. There has been no wave of competitive depreciations, perhaps because countries are alert to the dangerous and ultimately self-defeating characteristics of such behavior, perhaps also because the twin concerns of stagflation have brought about a certain symmetry in the pressures for depreciation to alleviate unemployment and for appreciation to alleviate domestic inflation.

Despite substantial fluctuations in exchange rates, the widely feared decline in international trade and investment has failed to materialize. Although the volume of world trade grew by only about 6 percent in 1971, well below the 1960–1970 average of 9 percent, this slowdown appears to have been related to the worldwide cyclical decline in output growth during 1970–71, rather than to the changes in the exchange rate regime which occurred in the second half of 1971. During 1972, the growth in the volume of world trade accelerated to 9 percent and then surged by more than 12 percent in 1973. All of these rates are in real terms; the growth in dollar values was substantially higher, particularly in 1973, when the dollar devaluation and the worldwide surge of inflation helped lift the dollar value of world trade to a level 37 percent above a year earlier. (See *IMF* 1974 *Annual Report,* Table 5, p. 13.)

The expansion of world trade has tapered off since about mid-1973, along with the slowdown of real economic activity in the industrialized countries. More fundamentally, changes in the volume of world trade in the period 1971–73 appear to have maintained essentially the same relationship to movements in industrial production or real *GNP* as characterized the previous decade or even two, suggesting that the costs associated with the conduct of international trade have not risen significantly during the period of transition to limited exchange rate flexibility.[17] Similarly, although data on a worldwide basis are not yet available for 1973, the flow of long-term investment between the United States and other countries, at least, does not appear to have been adversely affected by exchange rate variability per se. The net flow of *U.S.* long-term investment abroad increased by more than 20 percent in 1973 over the 1972 level, and the net flow of foreign long-term investment into the United States increased by nearly 200 percent.

V. In Summary

In trying to sum up what we have learned about the process of adjustment to exchange rate change, we find that this period of transition leaves us with more new questions than new answers, that we must be tentative about everything and dogmatic about nothing. On the one hand, the experience of 1971–73 suggests to us that flexible exchange rates need not signal a retreat into autarky nor lead to beggar-my-neighbor policies of competitive depreciation and that, in the case of the United States at least, they do "work" as an instrument of balance of payments adjustment. That is, a depreciation, despite an initial perverse effect, does appear to lead to an improvement in the trade, current account, and basic balances, and despite substantial fluctuations, the exchange markets do appear to be dynamically stable. On the other hand, greater rate flexibility is not necessarily accompanied by a reduction in restrictions on international transactions; it gives considerably less than complete autonomy to domestic monetary policies; and rate changes appear to have a larger feedback onto the domestic price level than had been generally anticipated, at least in the case of the United States.

Flexible rates offer no perfect reconciliation between the desire for world market integration on the one hand and the demand for autonomy of national policies on the other; they are at best a second-best solution in a world where the efficiency advantages of integrated markets and a single international money must yield place to nations' insistence on individual sovereignty in the determination of domestic economic targets and policy instruments. Whereas we are uncertain about the impact of different exchange rate regimes on the course of world inflation, there can be no doubt about the relationship in the other direction: there can be no alternative to rate flexibility in the presence of high and widely divergent rates of inflation among nations. In fact, the very existence of such divergent rates of price increase indicates that countries regard the costs of maintaining a common rate of inflation, as required by a fixed-rate regime, as excessive in terms of their domestic economic goals. Furthermore, there is a widespread recognition of the fact that a system of fixed parities could not have weathered successfully the economic shocks of the past two years, and that the alternative to substantial fluctuations in foreign exchange markets would have been nonfunctioning markets for substantial periods. One might characterize the present exchange rate situation as Winston Churchill is said to have characterized democracy: "it is the worst possible system, except for all the others."

---

[17] Makin offers some detailed regression analysis in support of this proposition.

DISCUSSION

Rudiger Dornbusch, University of Chicago: Marina v. N. Whitman has provided us with a broad-based and quite eclectic review of our knowledge. Her conclusion that we must be tentative about everything and dogmatic about nothing is perhaps unduly pessimistic, and I shall therefore concentrate in my remarks on those issues that I feel we can quite confidently make strong statements about.

The first issue about which we can be quite dogmatic is that balance of payments questions, and more narrowly trade balance questions, are issues in the realm of macroeconomics and that consequently any approach that does not cast the problem in that setting is at best misleading and more likely incorrect. Nobody, I believe, is on record questioning this fundamental proposition about the adjustment mechanism, but still the literature and policy discussion abounds with instances where the implication of that assertion is evaded by approaches euphemistically referred to as "partial equilibrium," whatever that may mean in a macroeconomic context.

The recognition that payments problems are macroeconomic problems raises doubt about two propositions that have recently attracted interest. The first is the J-curve—the suggestion that a devaluation in the short run causes a worsening in the trade balance to be followed subsequently by an improvement. Already in the framework of a crude elasticity approach, there is no presumption that such an outcome is inevitable. More fundamentally, however, there would not seem to be a macroeconomic relationship that would predict an increase in nominal spending relative to income as a consequence of an exchange rate change, inevitably and independently of monetary and fiscal policy. It is true, however, that theories of the short-run consumption function might shed an interesting perspective on the problem and that accommodating monetary and/or fiscal policy would surely contribute toward establishing why we observe J-curves.

A second proposition that has to be questioned concerns the alleged permanent relative price advantage for exports that would be retained from a devaluation. This is indeed an extraordinary suggestion since it is argued that an exchange rate change in and of itself exerts permanent real effects. As it stands, the only support for such an effect is permanent money illusion. Alternatively, with the appropriate macroeconomic support, an exchange rate change can and will have long-run real effects. In that context, however, the roles are essentially reversed. A change in the balance between income and expenditure is essential and an exchange rate change is helpful in effecting the necessary relative price adjustments via an increase in the price of traded goods rather than a deflation-induced decline in the price of home goods.

A macroeconomic perspective suggests that changes in absorption that are implied by changes in the trade balance will have systematic effects on relative prices. As a first approximation, the relative price of domestic goods will decline in terms of all traded goods in the surplus country while in the deficit country, where absorption expands, the relative price of nontraded goods will increase in terms of traded goods. These relative price changes are required in order to translate changes in absorption, part of which falls on nontraded goods, into a change in the trade balance.

The preceding line of argument can be used to establish how an exchange rate change, accompanied by a validating aggregate policy, will affect the "competitive position" of a country in world markets. The relevant reasoning is not so much that domestic exports become cheaper abroad and imports become more expensive at home—the relevant distinction is one between traded and nontraded goods. The improvement in the competitive position of domestic producers of traded goods derives from the fact that the reduction in absorption frees factors of production in the home goods industries and thereby lowers real factor costs to the traded goods sector, making its expansion profitable. Conversely, in the deficit country the expansion in absorption and the nontraded goods sector causes tightness in factor markets and renders traded goods industries less profitable by raising real factor costs in terms of traded goods.

The enhanced competitive position of the home country does not only extend to established traded goods. In fact, the reduced domestic absorption causes some goods to move from the home goods sector to become exportables as their relative price decline makes them sufficiently competitive to overcome tariff and transport costs. Conversely, on the importable side the reduced absorption contributes to increasing the size of the sheltered sector. The distinction between internationally traded goods and home goods is therefore not excessively sharp but provides, nevertheless, the basis for systematic relative price effects of changes in absorption.

From discussion of the transfer problem it is known that there is no presumption about the terms of trade effects of a redistribution of income. By analogy the redistribution of absorption that is implied by a trade balance change does not affect in a systematic manner the relative prices of traded goods: the home country's exportables do not become, as a matter of presumption, cheap or expensive relative to importables.

None of the preceding remarks is in any manner at variance with the "monetary approach" to the balance of payments. That approach most assuredly does not require the "small" country assumption nor the assumption that particular and unusual relations obtain between prices of internationally traded commodities. All it does assume—as does indeed any approach I am familiar with, and in particular the elasticity approach and the Keynesian model—is that the prices for identical traded goods are equalized between countries with due allowance for exchange rates, tariffs, and transport costs. If they were not equalized, there would be unexploited profit opportunities to be eliminated by arbitrage. The misunderstanding would seem to result from the use, in some expositions, of one-commodity models that were chosen to drive home the point that exchange rate changes have nothing to do with terms of trade changes.

The discussion of flexible exchange rates in Whitman's paper raises several important questions. I entirely share her suggestion that stock considerations are important in the determination of exchange rates and should go a step further to say that exchange rates are determined in the market for asset stocks and not in the market for flows of foreign exchange. This point was noted by Joan Robinson when she remarked that the exchange value of a currency depends on the amount of it in existence with sufficient allowance made for changes in the demand for money. Such a view of the determination of exchange rates is obviously far removed from a conception of the exchange rate as balancing a current account with an independently specified capital account. A further implication of the stock market view of exchange rates is the substantial scope for expectations in the determination of the exchange rate. Anything that affects the demand or supply of money will as a first approximation be reflected in changes in the exchange rate.

The autonomy for monetary policy that is provided by flexible exchange rates has long been recognized as a principal attraction of that exchange rate regime, but has perhaps, too, been exaggerated. There is no question that in the long run flexible rates allow a country to choose its own rate of inflation independently of the rest of the world. Differences in nominal interest rates will reflect differences in anticipated inflation rates and the implied appreciation or depreciation of exchange rates. Beyond that autonomy there is very little. Flexible rates will not insulate a country against real disturbances originating abroad, nor will they insulate a country against foreign monetary disturbances since the latter will, at least in the short run, exert real effects. Capital mobility will ensure the transmission of monetary disturbances by keeping anticipated real interest rates in line internationally.

WILLIAM J. FELLNER, Member of the President's Council of Economic Advisers: I shall first ask and try to answer a very specific question connected with policy decisions. Thereafter I shall suggest a more general conclusion which bears on the central theme of Marina v.N. Whitman's valuable paper.

Say a country needs to get rid of a trade deficit and say that this needs to happen because an external source ceases to be available for further financing (for a further acquisition of claims or further subsidization). We shall assume that the need to balance the trade account does not arise with such suddenness as to exclude the bridging of lags during a transition period. Now, define *resistance* of the deficit country's economy to the equilibrating effort at full utilization as meaning that, at least temporarily, *underutilization* (unemployment) becomes a by-product of the trade-equilibrating process. In the analysis I suggest here, this could happen because it is in practice impossible to make money wage rates consistent with the requirements of full utilization. The first question I will pose is whether resistance in this sense is or is not apt to be greater if in the deficit country demand is reduced in terms of the domestic currency under a fixed rate system than if the exchange rate of the currency is allowed to become reduced in response to market forces and the demand for goods is kept unchanged in terms of the currency of the country. (The assumption concerning strictly unchanged nominal demand can and will be somewhat relaxed.)

Under a properly functioning fixed rate regime the adjustment process will involve either a reduction of after-tax money wage rates (I mean a reduction relative to trend) *or* it will involve underutilization. In either event nominal and real balances will presumably be reduced. On the other hand, under a properly functioning regime in which the exchange rate of the deficit country is allowed to decline in response to market forces, the process is compatible with unchanging after-tax money wage rates and other after-tax money incomes and with a one-time increase in consumer prices expressed in terms of the domestic currency. Given the unchanging after-tax money incomes and the higher prices, trade will become balanced here too, with smaller imports and higher exports and presumably with smaller real balances (unchanging nominal balances). The process could even be described as involving a one-time increase in money wage rates that falls short of a one-time increase in the price level. From this it, of course, does not follow that in the case of rate adjustment there will be no resistance in the sense in which the term is here used, since *real* wage rates *will* have declined in either case. If for the time being the real decline is accepted only in a state of underutilization then the outcome will reflect resistance (in our sense) even in the case of rate adjustment. The first question that needs to be considered is, however, whether a difference in the degree of resistance can be expected when we compare these two ways of eliminating the trade deficit and, if so, whether the difference is to be attributed to mere "money illusion."

As I see it, a difference *is* to be expected quite aside from any money illusion that may exist. The reason for this is that, in countries in which collective bargaining plays an important role, a concern with *relative* real wage positions nevertheless gives the money wage bargain a special status. No union management suddenly called upon to accept a burden in terms of money wages knows what is about to happen to the relative real wage positions that have gradually evolved in the economy. This is true especially because a good many negotiated money wage rates are not even capable of being changed in the short run. On the other hand, it is true in an acceptable first approximation that, if the real burden is imposed in the form of higher consumer prices, real wage rates are reduced in the same proportion across the board.

This same distribution of the burden could "in principle" be achieved even under the fixed rate regime, but only if in the deficit country the deflationary effect were achieved by taxing all wage earners (and presumably other income recipients) in the identical proportion and by "destroying" the money so collected. Such changes in the tax structure could clearly not be achieved with the required promptness, all the less because only gradually could it be discovered what the size is of the needed taxation. The reserve-flow mechanism is rightly represented as working not through such tax changes but through pretax money income adjustments, and these do pose the question of how easily money wage rates give way piecemeal with unpredictable consequences for relative real wage positions. Thus it is reasonable to expect a higher degree of resistance at full utilization in the event of the fixed rate than in that of the flexible rate adjustment process.

The reasoning so far has assumed that neither the flexible rate system nor a system aiming for fixed rates is misused by governments with inflationary proclivities. However, postwar history has demonstrated that governments have a strong inclination to generate inflationary processes which provide a temporary stimulus to economic activity. Such policies provide a stimulus as long as the actual rate of inflation can be kept higher than the expected inflation rate with the result that the available real incomes are overestimated by the public. This has been happening even though the price that needs to be paid for such policies subsequently is uncomfortably high. The flexible rate system can be misused by governments with such inflationary proclivities and systems based on other principles also can be. How?

In a flexible rate system a deficit country can engage in inflationary policies by which money wage rates are allowed to rise progressively at high utilization levels in circumstances where an underestimate of the inflation rate by the public—hence an overestimate of real wage rates—creates the belief that an inevitable burden is being avoided. The one-time price increase that would take place under a properly conducted flexible rate adjustment process degenerates into an accelerating inflationary process to which at a later stage it will be necessary to put an end at a considerable cost in terms of the rate of resource utilization. Meanwhile rate adjustments will presumably repeat themselves. A flexible rate system misused by inflationary practices is clearly inferior to a fixed rate system that is not misused by governments with strong inflationary tendencies.

Yet there exist methods by which systems based on the fixed rate principle can also be so misused, and if misused, these systems are also apt to lead to very bad results.

One such method of misuse is that of endowing a fixed rate system very richly with reserves and of letting the adjustment processes develop exclusively by means of inflation in the surplus countries. This imposes more inflation on the surplus countries than the amount which their own political processes would make inevitable. And given sufficiently ample reserves, there is no presumption that the trend in the deficit countries would become less inflationary than the initial political pressures in those countries would have required. This is one method of misusing a fixed rate system.

The other method by which systems based on the fixed rate principle can be misused is that of introducing escape clauses that enable countries to administer abrupt exchange rate modifications in circumstances in which flexible rates would have moved gradually. When misused by either of these methods, or by a combination of the two, such a system yields no better results—probably yields worse results—than a misused flexible rate system. The past provides many illustrations for the misuse of both systems.

It is essential to ask oneself the question what a government is capable of achieving if it has learned from past experience and has developed a firm intention not to misuse the currency system, though it may prove incapable of standing up against political pressures if these become too acute. I suggest that in the contemporary environment the pressures against which a competent government trying to play the game according to the rules will have to stand up are greater under a system aiming for fixed rates than under a system leaving room for rate flexibility in response to market forces. Standing firm against pressures to generate a self-defeating inflationary process, difficult as it may be, should nevertheless be much more manageable than generating a deflationary process which hits the individual elements of the wage structure piecemeal, and partly with a considerable lag, as wage negotiations come up for renewal.

In an uneasy world we have arrived at an uneasy case for flexibility. But the case is a lot less uneasy than is that for a system that would try to establish fixed rates in the present circumstances.

ALEXANDRE KAFKA, International Monetary Fund and University of Virginia: As the only underdeveloped member of this panel, I should like first to say a few words about how different exchange rate regimes may affect many of the less developed countries (*LDC*). I shall then make some general observations on our subject.

The *LDC*s have been concerned because the progressive abandonment of the par value system, as Marina v. N. Whitman shows, has meant not only medium-term realignments of average exchange rates among industrialized countries but also large short-term fluctuations. A par value system (as distinct from a fixed rate system) could not have avoided the medium-term realignments, but could have avoided the short-term fluctuations.

What are the problems which the floating of the currencies of industrialized countries creates for some *LDC*s? Those among them who do not peg to another country's currency may face problems of learning and institutional adaptation, involving at least transitory additional social costs, when major currencies fluctuate to a larger extent than under the par value system. First, an exchange rate policy may have to be instituted, i.e., decisions may have to be taken whether to peg to a single currency, to a basket of currencies, allow the currency to float freely (whatever that may mean), etc. Second, forward markets may have to be created where they previously did not exist. This can be avoided by pegging to a single currency; and such pegging may in any case be unavoidable for reasons of economic size and tradition of the pegging country. But pegging to a single floating currency may involve disagreeable political decisions as well as balance of payments and internal stabilization problems additional to those faced under a par value regime.

*LDC*s also fear that they may be confronted by a problem of reserve supply if major currencies continue to float. John Williamson has suggested that countries pegging to a floating currency (which is the case of most *LDC*s) are likely to experience increased reserve use and reserve needs. The reason is the likely increase in the variability of their receipts and payments, if the currency to which they peg fluctuates in terms of third currencies and if their trade is partly with third countries. If, by contrast, increased exchange rate flexibility among major countries reduces or, at least, does not similarly increase their reserve needs, the propensity to create reserves for the world as a whole will become inadequate from the point of view of *LDC*s pegging to a floating currency.

As against these inconveniences, *LDC*s would very much agree with Whitman that the recent type of floating has not clearly led to reduced restrictions—though admittedly nobody knows what would have happened in the absence of floating.

I agree with almost—but not quite—everything else that Whitman says in her truly excellent paper about the subject of our panel. I have three areas of doubt.

First, her description of the present system as a managed float (with relatively little intervention) is certainly correct. Perhaps, however, the management is, so far, even a little less disorderly than she suggests. Intervention takes place subject to consultation and is not at cross purposes. Even other policies are applied to some extent in accordance with internationally agreed principles. Thus, international borrowing is in accord with the principle that oil deficits as a whole must be financed at this time since to attempt to adjust them would be futile. We have also a set of internationally agreed guidelines for floating designed to avoid competitive exchange rate changes and, in addition, to permit the International Monetary Fund (*IMF*) to encourage (but not to oblige) countries to keep rates somewhere within a sensible range in relation to each other if there should be a tendency which might move them away from such a range. So far, these guidelines have at least not been obviously flouted by any country. Admittedly, however, the temptation to do so has been smaller than it is likely to be in the near future.

That we should have a managed float is hardly surprising. Since modern governments bother about prices, they can hardly be expected not to bother about exchange rates and not to try to control them. One aspect of this concern refers to the effect of the exchange rate on the structure of the balance of payments: if adjustment is possible, a deteriorating current account may be bothersome even if overall equilibrium is preserved due to capital inflows with an appreciating exchange rate. From the international point of view, and contrary to the conventional view, "free" floating is even more difficult than managed floating to police as an international system. Anything a government does—not just exchange market intervention—is likely to affect the exchange rate. And one can never be sure whether a policy was designed to alter the exchange rate or not, so that one can never be sure whether the adoption of any policy contravened an agreement not to manage a float. Under managed floating, there can at least be an agreement to encourage or even oblige a country to keep its exchange rate within a sensible range.

Second, the system has not avoided large short-term fluctuations of rates. But—and even more important—one may also doubt its ability to bring balances of payments closer to equilibrium. Whitman shows that it has done so for most balance of payments concepts in the case of the United States (except for the oil impact) but, as C. P. Kindleberger reminds us in a recent lecture, emphatically not in the case of Germany (despite the oil impact). Did effective exchange rate movements not produce the same effects in Germany as in the United States? Or did the deutsche mark effective rate, for some reason, fail to move adequately (considering not only divergent price movements but also, e.g., divergencies in delivery terms)? Was such a failure due to slight but misplaced intervention outside the mini-snake, or to the persistence of some controls affecting capital movements, or to the need to give speculators time to learn how to speculate under floating rates? One must hope it was not the latter, as recent rate movements do not suggest that much learning is taking place. Or must one simply conclude that major divergencies between countries in demand management policies and cost-push, such as existed between Germany and her major trading partners, are apt to mean that fluctuating exchange rates do not work well? But par values also work well under ideal conditions.

My third doubt concerns the relationship between worldwide inflation and the exchange regime. Floating rates, including rates subject to some management, would, according to traditional theory, be expected to bottle up inflation (or deflation) in the country where it originates (and give other countries greater policy autonomy). Of course, worldwide inflation does not imply that inflation has spread, despite floating; domestic inflationary pressures may have just happened to be simultaneously present in countries whose currencies were floating. In fact, however, floating rates may actually contribute to the spread of inflation, a point made first, I believe, by Marcus Fleming and which reinforces Whitman's own skepticism. Theory teaches us only that floating rates would isolate economies in the absence of capital flows. If, however, capital is sufficiently mobile, a boom and inflation in one country may attract it in such large quantities that that country's exchange rate appreciates instead of depreciating. Thereby it spreads the boom and inflation to other countries even more than would be the case under fixed rates and gives other countries even less policy autonomy.

Where does this leave us? Certainly not necessarily with a preference for a par value system at this time, but with a preference for a system which replaces par values by an obligation to maintain exchange rates not within fixed margins but within zones with soft margins. In other words, a more specific obligation than that involved in *IMF* guidelines might well be preferable: vouchsafe more stability than the present system and yet handle at least as well exchange rate changes required in present unsettled conditions. The more specific obligations mentioned may appear more necessary as temptations to flout the *IMF* guidelines increase.

Kindleberger in a recent lecture spelled out the difficulties one meets in making up one's mind about how well any given system has worked, let alone about how well it is likely to work in the future. But even apart from his warnings, on the grounds given earlier, it seems to be difficult to agree with Whitman's conclusion that the system which has emerged "is the worst possible system except for all others." One will have to be even more undogmatic than she is. There is no proof that any other system would have been better, but there is certainly none that all others would have been worse.

Paul A. Volcker, Princeton University: Marina v. N. Whitman seems to me properly modest in summing up for the profession what it has learned so far from the recent experience with flexible exchange rates. Indeed, a practitioner in the area might be excused for noting a sharp contrast between the tone of authority with which most economists pronounced policy judgments about flexible exchange rates on the basis of theoretical constructs before 1971 and the tone of humility that emerges from attempts to assess actual experience with such a regime since that time.

To be sure, Whitman reassures us that, "in the case of the United States at least," the evidence is that movements of exchange rates do have the anticipated effects on the direction of the current account adjustment. Exchange markets therefore appear "dynamically stable," at least in the limited sense that exchange rates, left to themselves, will not oscillate between zero and infinity. But we are still left pretty much in the dark about the relevant elasticities and lags involved in exchange rate changes.

In the midst of this "scientific" uncertainty, the disconcertingly large fluctuations in market exchange rates over the past two years are perhaps not surprising.

Indeed, the now properly fashionable technique of calculating trade-weighted "effective exchange rates" obscures, as Whitman implies, the degree of instability we have seen in important exchange markets. Movements in "effective rates," particularly for the dollar, are dampened by the practices of some countries in formally or informally pegging their currency to the *U.S.* dollar, or by the relative stability of rates between some closely linked economies where historical "parity" relationships seem normal. Meanwhile, exchange rate relationships between the most important world traders—the United States, Germany, and Japan, each of which compete in world markets over a broad range of manufactured goods—have gyrated through a range that, on the face of it, bears little resemblance to changes in domestic price and cost structures.

For instance, deutsche marks today buy 65 percent more dollars than they did in 1969; and at one time in 1973 about 75 percent more. Yet, in between, they temporarily lost over 20 percent of their peak dollar value. Perhaps more understandably, the yen appreciated at one point by 42 percent vis-à-vis the dollar, but then fell back by over 12 percent in the space of a few weeks. We can find more extreme examples among the cross rates for such important and close trading countries as Italy, the United Kingdom, Switzerland and the Netherlands.

If economists are highly uncertain about the size and timing of the impact of exchange rate changes, why should they (of all people) expect stabilizing speculators—some never very clearly defined group with access to large resources—to be quick to put not just their professional judgment but real money on the line? At least on a bandwagon you have the psychological comforts of good company and loud enthusiasm in return for the price of admission.

Of course, we must not forget we are in a transitional and learning period. Disequilibria had accumulated over years, and the world economy has been buffeted by unprecedented disturbances from oil, food, and inflation. In time we should be able to look to the economist for more reliable answers to the open questions—and to businesses and banks for more efficient speculative stabilization. But I do not know how much time we have. Until recently we have had a high level of mutual prosperity and common concerns with shortages and inflation. These provided powerful incentives to maintain open import markets. Businesses, pressed to deliver and obtain materials, have worried more about availability than price. As we turn to preoccupation with recession, unemployment, and payment for oil bills, new doubts and questions seem likely to arise about how well floating exchange rates reconcile the desire to maintain a high degree of international integration, ease adjustment problems, and preserve autonomy for domestic policies.

Concern over the present functioning of the market is not enough. What is the alternative? The present state of economic knowledge seems to support the instinctive reaction on nearly all sides to rule out an early return to a fixed rate regime. Whitman has demonstrated how little we would have to go on in establishing new fixed rates, and in changing them at discrete intervals, especially in a world where there is no *n*th country willing and able to play a relative passive role, absorbing any residual deficit that might result from letting other countries "play it safe" by resolving their own doubts on the side of surpluses. The credibility of new fixed rates would require a commitment of official financial resources and a willingness and ability to coordinate internal policies to a degree that simply does not now exist.

But conversely, the elasticity doubts and the possibly long lags associated with adjustment to exchange rate changes—to say nothing of new doubts raised about the internal price repercussions of exchange rate fluctuations—reinforce concern that large overshoots may be characteristic of more or less free floating and bring in its wake large and unnecessary dislocations in both domestic and international markets. Because our foreign trade sector is so small (although growing) relative to the total economy, and because of concern that official intervention can be overwhelmed in the context of large and open capital markets, the temptation has perhaps been strongest in this country to live with these uncertainties and distortions as the price of domestic autonomy, meanwhile awaiting more settled conditions and the stronger appearance of the benign speculator. But Whitman makes clear we are in the midst of a new debate over how much autonomy even the United States has gained.

We have learned, for instance, that in conditions of strong demand and price pressures, with important export- or import-competing industries already experiencing capacity and shortage problems, a depreciation may result in more price pressure and less balance of payments adjustment than bargained for.

In the end balance of payments adjustment (to the extent it cannot be achieved through capital accounts alone) requires a shift of resources, and that shift has domestic as well as international consequences. In a given economic and political structure (say the United States) it may sometimes be easier to accomplish that shift with less pain (real or observed) if the shift initiates in the relatively obscure manner of changes in import and export prices. At other times, or in other countries, the relative advantages may be different—and a monetary *system* must serve the needs of more than one country.

Whitman questions particularly whether the vaunted independence for monetary policy in a regime of floating rates has not turned out to be a good deal less than promised. No doubt it will be a long time before we have the final word on this subject. But observation of recent events suggests we have a slower and more uncertain real adjustment process, a much larger supply of interest-sensitive (and bandwagon) capital relative to changes in current accounts, and less courageous benign speculators than most theorizing about independence for monetary policy presumed.

Whitman has put her finger on the weakness of expectations concerning future exchange rates as explaining the absence of stabilizing capital flows and the instability of observed exchange rates. A little later, she argues uncertainty concerning future rates is crucial to independent monetary policies. If she is right, we can't have it both ways—floating cannot at the same time give us reasonable stability and autonomy. Some clarification is needed, but in the end, I cannot square the circle—we will have to compromise.

Take the case where future expectations are weak or absent. Disturbance of an equilibrium by a change in relative interest rates, providing an opportunity for a known gain in interest returns, will presumably stimulate some uncovered capital movements and thus a change in present exchange rates. The initial exchange rate change is as likely under these conditions to attract followers as counterspeculation. If the interest differential persists, so should the pressures on exchange rates—and the market may well anticipate the changes in abrupt movements.

The process will presumably be self-limiting, but only at considerable cost. Substantial exchange rate changes would be necessary to induce strong expectations that the existing rates are too high or too low, ending incentives to net capital flows. Eventually, large changes in current accounts would develop to the point that real rates of return on capital are affected, a new equilibrium in interest rates forced, and the process reversed. Obviously, this kind of corn-hog cycle in exchange rates would be cumbersome and the costs in terms of international integration high. In specific circumstances, a country easing or tightening monetary policy may willingly accept or welcome the consequences for the current account as reinforcing the objectives of monetary policy. But carrying that process very far invites "beggar-my-neighbor" (or "inflate-thy-neighbor") descriptions.

Now take the case of strongly held future expectations. In this case a "collar" is placed on the deviation of the present exchange rate from the future expected rate, roughly measured by the relevant interest rate differentials. At first blush, this seems to be ideal, for domestic monetary autonomy is achieved with limited exchange rate repercussions. The trouble seems to me that, if the future expectations are not borne out by experience, they eventually will be dropped. And those expectations are not likely to be borne out if monetary policies, among other factors, remain divergent. It is in that sense that Whitman seems to me correct that certainty about future exchange rates is inconsistent with autonomy in domestic policy—it promises more than can be delivered.

I am forced to the mundane conclusion that, in an integrated world, domestic policy autonomy is a will-o'-the-wisp, whatever the exchange rate regime. What does of course differ is the manner in which a domestic policy initiative or other disturbance affects different sectors of the home economy and is transmitted abroad—particularly the degree to which adjustment is forced initially on the foreign trade sector. Different countries will perceive their interests differently in this respect, so compromise is called for. At the same time, nobody has an interest in the repetitive undershoots and overshoots inherent in unformed expectations. Both considerations suggest a strong common interest among the relevant authorities in providing more leadership toward solidifying future exchange rate expectations than has been apparent.

In general terms, my proposition is that floating needs management; because we are starting in such disturbed circumstances, the management needs to be substantial; and to be credible and effective, the management needs to extend beyond direct or indirect exchange market intervention into all the old ground of coordination of monetary and other policies. In time, as our domestic economies become more stable, and as we and the markets learn more about what exchange rates are consistent with balance of payments equilibrium, we might anticipate the need for management, certainly in the sense of intervention, to progressively lessen. At that happy stage, the operational distinction between managed floating (soft bands) and readily adjustable pegs (hard bands) could more or less wither away.

I do not suggest this is analytically, operationally, or politically an easy approach. It does not have the simplicity of the free floating or the fixed options. If governments and central banks are to step up to take the risks that stabilizing speculators now refuse, and if they operate with some intelligence and understanding, they should be rewarded over time by financial gains from performing an important social function. But the risk of financial loss (to say nothing of loss of face) is apparent. However much economists may be inclined to dismiss the matter as bookkeeping, this matter is a large deterrent to action—perhaps more in the United States than elsewhere.

Assessment and sharing of these risks lead directly into the broader question of the division of responsibility (and judgment) for intervention, and for reasonable coordination of monetary policies, between nations on the opposite sides of the same exchange rate. The convenience of an *n*th country, passive in exchange rates but powerful in monetary policy, will likely disappear as part of the process because it no longer fits the economic power relationships or the political sensitivities. Fortunately, the really key actors are relatively few, and they can approach the problem with a good deal of informality. But, as the process becomes multilateral, the whole range of issues involved in formal international monetary reform arises.

My responsibility today is for a brief comment on what we have learned from recent experience, not an essay on monetary reform. So I will conclude simply by saying that I see nothing in what has happened that detracts from the need and urgency to complete the reform effort—or that makes the job seem any simpler than before.

25 YEARS AFTER THE REDISCOVERY OF MONEY: WHAT HAVE WE LEARNED?

Recent Developments in Monetary Theory

By STANLEY FISCHER*

The revolution in the significance attached to the role of monetary factors in the determination of the price level and rate of economic activity in the last twenty-five years is empirical, not theoretical. Comparison of Franco Modigliani's 1944 exposition of the Keynesian system with Milton Friedman's 1970 framework for monetary analysis reveals little change in the basic short-run macroeconomic model. Nonetheless, monetary theory today is very different from that of twenty-five years ago; the major change lies in the shift from comparative static analysis to explicitly dynamic analysis of the impact of exogenous variables on prices, interest rates, and, where variable, employment.

Because Harry Johnson's excellent 1962 survey comprehensively covers earlier developments, I will concentrate in this paper on those branches of monetary theory which have undergone most of their development over the last decade. In Sections I–III, respectively, I discuss work on the new microfoundations of money; disequilibrium theory; and money, price dynamics, and growth. The rational expectations hypothesis, and its implications for price dynamics, is taken up in Section IV, with conclusions presented in Section V.

There are also some noteworthy omissions. The most significant from the viewpoint of macroeconomics is the new microeconomics of unemployment and the Phillips curve which is not discussed since money is not directly involved in most of the models. Space limitations force me to define developments in the theory of policy and applications of control theory to macroeconomics as empirical; further, given my emphasis on the novel, I do not discuss some important extensions of earlier work on portfolio theory, the demand for and supply of money, and the term structure of interest rates.[1]

I. The New Micro Foundations of Money

Monetary analysis typically starts from an informal and usually picturesque explanation of the use of money, involving the double coincidence of wants and the four functions of money. A demand for money is then postulated and money is treated as one of the assets in a macro model, distinguished from other assets in one or more ways: since money is the medium of exchange demanded for its command over goods and services, the demand is a demand for real balances;

I am grateful to Jacob Frenkel, Milton Friedman, Pentti Kouri, Huston McCulloch, Franco Modigliani, Mary Kay Plantes, William Poole, Robert Solow, Ross Starr, Lars Svensson, and Hal Varian for helpful discussions and comments.

[1] Space limitations also require the number of references to be limited. A longer version of this paper with a more complete bibliography is available from the author on request.

since it is a medium of exchange, the real income elasticity of demand is positive; its interest return may be fixed exogenously; its nominal quantity, if it is a fiat money, can be exogenously determined.

The criticism "that the foundations of monetary theory have not yet been laid" turns primarily on the argument that there is no role for money in macro models, which are all small Walrasian general equilibrium models.[2] Essentially, it is argued that there is no role for money in intertemporal general equilibrium models since all trades in such models can be arranged in the first period the auctioneer opens the market; alternatively, within each trading period, there is no obvious need for a medium of exchange since all trade takes place with the market at equilibrium prices. Even if it is assumed that trade is between individuals rather than with the market, the theory offers no reason why one good rather than another should be used to balance trade between two individuals whose needs do not doubly coincide—nor does it offer a good reason why trade should balance between individuals. While these are compelling criticisms of the general equilibrium model as a description of modern economies, their practical import applied to the standard macro models is less clear, since several features of the demand for money in such models do reflect the medium of exchange function of money.

Recent literature on the foundations of monetary theory has attempted to make precise the notion of the double coincidence of wants; to present criteria for the selection of the medium or media of exchange (also, under the guise of "portability," "divisibility," etc., a concern of the early monetary theorists); and, fundamentally, to explain how it is that the use of money enables an economy to attain equilibria which are not possible without money. Three approaches can be distinguished. The first takes equilibrium prices for a single period as given and investigates the possibility and number of exchanges required to attain the implied equilibrium allocation of goods under various constraints on the exchanges that can be made when all trading is strictly bilateral. The second examines single period exchanges in an economy in which transactions are costly and determines market equilibrium and the nature of exchanges for that economy. The third uses a multiperiod general equilibrium framework in which exchange within periods is with the market, but in which money can be useful in making intertemporal transfers. Transactions costs and/or informational considerations are involved in all the analyses. Many of these analyses can be viewed as developments of work by Sir John Hicks, attempting to relate traditional explanations of the use of money to Keynes's three motives for holding money.

In most of the contributions in this area, money makes possible the attainment of equilibria which are otherwise unattainable by permitting the unbalancing of budgets in goods within a period or transaction. The reasons for balance at each transaction are elucidated by Joseph Ostroy and have to do with restrictions on the information which an individual is likely to have about other traders' solvency and the saleability of goods taken in exchange. Those models, such as Hahn's, which concentrate on intertemporal market equilibrium, do so because it is argued that the sequential nature of exchange is important, but then implicitly allow simultaneous trade within a period.[3] Indeed, they provide more reason for the use of bonds than for the use of a medium of exchange.[4]

---

[2] See Frank Hahn (1973a, p. 233). This article is a useful survey of one branch of the modern literature.

[3] See Hahn 1973b. An influential paper by Roy Radner emphasizes the sequential nature of transactions and the importance of the unfolding of new information over time.

There are few formal attempts to explain the emergence of money from barter systems; Mordecai Kurz argues that this social choice is fundamentally not analyzable by conventional economists' methods. Analysis of the structure of transaction costs leading to the adoption of some commodity as money, as in Jurg Niehans, is at least likely to restrict the choice of media of exchange, and work by Robert Jones provides an interesting start on the dynamics of the emergence of a medium of exchange. The literature mentioned so far has assumed nonincreasing returns to scale in transactions, though there are attempts to study money in nonconvex transactions technologies. The relationship between the existence of organized markets and the use of a medium of exchange is as yet unclear. Nor has uncertainty been given a prominent role in any of these models, except in Karl Brunner and Allan Meltzer.

This work is obviously both difficult and only a beginning. It is not clear where, if anywhere, it will lead. It will no doubt provide more convincing and carefully worked out explanations for the use of a medium of exchange than we now have, but it appears that those explanations will not be fundamentally different from the traditional verbal explanations, and that they will not have any major consequences for the way in which macromodels are built.

II. Disequilibrium Theory

The interpretation of the Keynesian system as an equilibrium system, except in the labor market, had become widely entrenched in the textbooks by the 1960's, in the shape of the familiar IS-LM apparatus. The apparatus was strongly criticized as essentially non-Keynesian by Robert Clower and Axel Leijonhufvud. I shall avoid the exegetical issue since the Clower-Leijonhufvud criticisms of the income-expenditure model, which have been followed by extensive work interpreting the Keynesian system as a disequilibrium system, are of independent interest.

Leijonhufvud's fundamental criticism is that income-expenditure theory suffers from auctioneer illusion. The informational problems the Walrasian auctioneer solves in obtaining an equilibrium price set are not, Leijonhufvud says, costlessly or immediately solved in the real world; they produce disequilibrium, trading at false prices, and unemployment—and, further, informational problems are complicated by the use of money. In particular, for reasons explored in the Edmund Phelps volume, quantities adjust more rapidly in response to disturbances than do prices and trade accordingly takes place at disequilibrium prices.[5] Disequilibrium trading produces deviation-amplifying (multiplier) effects on quantities which are absent from the typical Walrasian model. The work to be discussed below makes the basic Leijonhufvud position more precise.

The distinction between notional and effective demands is critical in disequilibrium analysis. Notional demands and supplies are calculated by individuals and firms on the assumption that they can buy and sell as much as they want of any good at prevailing prices. This assumption can be true only in equilibrium. In disequilibrium there are constraints on the amounts of some goods an individual can buy or sell. Effective demands are calculated conditional on the quantity constraints, or any other nonprice constraints, the individual perceives. For instance, if there is an excess supply of labor, the effective demand for goods by an individual who cannot sell as much labor as he wants is less than the notional demand for goods at prevailing prices. Further, his demand for goods in that situation will be a function of the amount of labor he can sell. This is the essence of Clower's dual decision hypothesis in which one set of demands is expressed if markets clear and another set if individuals are constrained. Clower applied his analysis to the consumption function, thus justifying again the Keynesian consumption function with income rather than the real wage as an argument.[6]

---

[4] It may well be, though, that only trivial transaction costs account for the failure of bonds to be used as medium of exchange. See Walter P. Heller.

[5] The Phelps volume (1970) was published after Leijonhufvud's book, but the article by Armen Alchian in the former is repeatedly referred to in the latter.

The most useful definition of effective demands is not yet settled. For instance, Herschel Grossman assumes that individuals express demands in each market which are based only on the quantity constraints perceived in other markets. Thus the effective supply of labor when the individual is constrained only in the labor market is the notional supply. This is a convenient but not compelling hypothesis. It also implies that effective demands do not necessarily obey Walras' law.

An analysis of the behavior of firms in demanding labor when they are unable to sell all the goods they want to at the prevailing price level had earlier been provided by Don Patinkin (Patinkin, ch. 13). In that situation firms' demand for labor is a function of the level of demand rather than the real wage. The Clower and Patinkin analyses are combined by Robert Barro and Grossman in a simple model with one perishable consumption good and money; households supply labor, purchase goods, and can attempt to save by adding to real balances. Firms hire labor to produce goods and both firms and households take prices as given.

For any specified wage and price levels, except at the Walrasian equilibrium, firms and/or households will be constrained in some markets. In particular, on the assumption that quantities are determined by the minimum of effective supply or demand in each market, there exist wage and price levels at which there are excess effective supplies of both labor and goods.[7] In such situations, the Keynesian cross becomes the model of output determination, and any change in demand (caused, say, by an increase in the nominal money supply) has the full multiplier effect on output—provided the change does not move the system into a different configuration of excess effective demands. Significantly, for this Keynesian case to prevail, the real wage may even be below the Walrasian equilibrium level if the absolute price level is so high as to reduce the effective demand for goods below the equilibrium level, through the real balance effect.

What does money have to do with all this? Leijonhufvud argues that the fact that the offer to work takes the form of a demand for additions to money balances rather than goods is crucial in generating the disequilibrium states. In a one-factor model in which the only market is one in which labor trades for a single good, it is, of course, possible to have unemployment if the real wage is too high. It is also clear that unemployment can arise at disequilibrium prices—and probably even at a real wage below its Walrasian equilibrium level—in models with many goods but no money. The role of money in disequilibrium trading is studied by Jean-Pascal Benassy. In any event, it is clear that the argument that money is crucial in generating disequilibrium cannot be studied in a model with exogenous prices.

---

[6] The classical life-cycle and permanent-income theories do not explicitly include the labor/leisure choice and thus treat income as predetermined.

[7] The fact that households can plan to save by adding to real balances is important in this regard.

Expectations are obviously important in disequilibrium analysis. To the extent that current unemployment is regarded as transitory, effective demand will be little reduced by constraints in the labor market as individuals draw down assets, if they have them, to maintain consumption; these expectational effects are made explicit in Barro and Grossman's forthcoming book in which the consumer's choice problem is set in a life-cycle context. The role of capital market imperfections and the distribution of unemployment relative to asset holdings of the totally unemployed in determining the size of the multiplier are studied by John Flemming.

The Walrasian assumption that prices move instantly to clear markets is replaced in disequilibrium analysis by the assumption that quantities can move instantaneously while prices remain fixed. Thus a discrete change in the stock of money or expectations, say, results in instantaneous movements in output in these models. The outstanding problem in macroeconomic disequilibrium theory is the working out of joint price and quantity determination.[8] The large search-theory oriented literature on price determination by firms which involves uncertainty—not so far embedded in the macrodisequilibrium analyses—will undoubtedly play a role in this synthesis. While disequilibrium analysis has succeeded in presenting models in which many Keynesian notions—particularly that of effective demand—are clarified, it remains to be seen whether the same analytical structure will prove useful when applied to situations in which price determination is endogenous.

III. Money, Price Dynamics and Growth

Recent emphasis on the dynamics of the adjustment to changes in the stock of money and its growth rate can be regarded as a return to themes of David Hume and Irving Fisher. Since much of the recent work has been set in a growth framework, I shall begin by outlining the framework and the uses to which it has been put. The major questions discussed in the money and growth literature are the "superneutrality" of money—in particular, the relationship between the steady-state rate of inflation and capital intensity—and the stability and more detailed dynamic properties of the processes of inflation and capital accumulation.[9]

In the simplest neoclassical growth model, as presented by Miguel Sidrauski, in which there are only one good and two assets, money and capital, equilibrium capital intensity is greater the higher the steady-state rate of inflation (Sidrauski 1967b). Money is injected into the economy through government transfer payments and the basic result occurs because a fixed savings rate is applied to disposable income: the injections of money have to be saved and displace some capital from portfolios. This result is due initially to Tobin (1965).

The basic Tobin-Sidrauski result can be reversed in descriptive models in a number of ways. First, if income in the monetary economy includes the imputed services of real balances, savings may fall sufficiently as the rate of inflation rises to offset the concurrent portfolio shift towards capital which otherwise increases capital intensity (Johnson 1969). Second, the result can be reversed by including real balances in the production function—as shorthand for the fact that the use of money in transactions frees real resources for the production of goods.[10] Third, the result depends on the assumption that money is of the outside variety.

---

[8] Barro and Grossman in their book append the "law of supply and demand" to their static model to discuss the dynamics and stability of their system which may not converge to the Walrasian equilibrium. Assumptions about the demands expressed in markets which do not clear—discussed in the above text—are obviously important in this regard. See Katsuhito Iwai for an analysis of joint price and quantity determination.

[9] Money is superneutral when steady-state real variables are independent of the growth rate of money.

The dynamics of inflation in monetary growth models depends heavily on the assumed process of expectations formation and the implicit or explicit reasons that prices change in the models. In neoclassical models, prices change to maintain portfolio equilibrium—to equate the demand for nominal balances, which may itself be represented by some distributed lag scheme, to the supply of nominal balances. In Keynes-Wicksell and other models, prices may change because they are expected to and/or because there is excess demand in the goods markets. Similarly, a wide variety of plausible expectations assumptions has been used. The way in which prices, real and nominal interest rates, and (where variable) the unemployment rate adjust to monetary changes depends on the details of the price-adjustment and expectations assumptions; it appears that almost any pattern of adjustment can be obtained by a suitable and not implausible choice of expectations and price-adjustment equations. Thus in this area, which is crucial from the policy viewpoint, existing theory seems to offer too much—the need is to restrict the class of acceptable results. Fortunately, certain restrictions are implied by the stylized facts emerging from the extensive empirical work in this area.

The indeterminacy of the basic results of the descriptive growth models, as well as the view that models should be based on optimizing behavior, leads naturally to attempts to restrict behavioral functions by appealing to models of individual optimization. In the initial such optimizing model, in which money enters the utility function and maximizing is over an infinite horizon, the steady-state capital stock is invariant to the rate of inflation (Sidrauski 1967a). This strong result is not, however, especially robust: treating money as a factor of production, or making the labor/leisure choice endogenous changes it.

The Sidrauski optimizing model can be used to answer the question posed as the optimum quantity of money: What steady-state rate of inflation maximizes steady-state welfare? The answer, provided by Friedman (1969), is: that rate of inflation which makes the nominal interest rate zero. This usually negative rate of inflation satiates money holders with real balances which, since money is superneutral, are costless to produce; it may be necessary to impose lump sum taxes to reduce the money stock at the required rate. For a variety of practical reasons, Friedman does not follow through on the logic of his argument by proposing that policy go so far as to aim to achieve the necessary rate of deflation.

A frequent objection to the optimum quantity of money conclusion is that increases in real balances would displace capital accumulation, as occurs in some of the descriptive money and growth models. This displacement is difficult to demonstrate in certainty models in which individuals optimize over an infinite horizon. Tobin (1968) suggests using a model with overlapping generations and uncertainty in an attempt to begin to analyze the question of the effects of alternative government policies on capital accumulation. His interesting lead has not, to my knowledge, been followed up. The issue is closely related to that of the burden of the debt, in which it can be shown that the debt is a burden in life-cycle models but not in a model of optimization over an infinite horizon.

---

[10] These points are elucidated in papers by David Levhari and Patinkin, and Rudiger Dornbusch and Jacob Frenkel.

The major lesson of the optimum quantity of money literature, which is closely related to the much older literature viewing inflation as a tax on real balances, is that economists have little basis for discussing desirable rates of correctly anticipated inflation: the only cost of such inflation appears to be liquidity costs, which are small. An urgent order of business remains clarification and quantification of the costs of inflation discussed by Phelps (1972).

I conclude this section by mentioning a method of analysis—temporary equilibrium analysis—rather than a particular problem. The method is in fact typically used by monetary economists; equilibrium is established on existing markets conditional on expectations about the future and on stocks inherited from the past. A similar framework has recently been used by general equilibrium theorists to study problems of monetary theory, such as the quantity theory of money and the classical dichotomy (Jean-Michel Grandmont and Yves Younes, 1972) and the optimum quantity of money (Grandmont and Younes, 1973). The basic existence result in these studies is that equilibrium will not exist if expectations of future prices react too strongly to changes in current prices.

The ambiguity of most of the results discussed in the money and growth literature is distressing to the theorist, though no doubt cheering for the econometrician: numerical values of parameters do matter. Some conceptual problems have been clarified in this literature—for instance, the relationship between stock and flow equilibria (Josef May and Duncan Foley and Sidrauski). Problems requiring further research—price dynamics, expectations, and the micro foundations of macro models—become painfully clear in the development of the literature. None of these, however, is inherently related to growth.

IV. Rational Expectations

The dependence of the dynamics of the price level on the process of expectations formation is obvious from the literatures on money-and-growth and the new microeconomic foundations of inflation (Phelps 1970). In the money and growth literature, each assumption about expectations of inflation implies a different path for inflation. Although adaptive expectations have been widely used, explanations for their use are few: adaptive expectations seemed reasonable and proved useful in explaining data, as in Philip Cagan's pioneering work on hyperinflation. However, even in Cagan's model, adaptive expectations are systematically wrong in predicting, say, the behavior of the inflation rate in response to a change in the growth rate of money.

The rational expectations hypothesis is that the expectations of economic agents are the same as the predictions of the models in which they are assumed to be actors. Thus the hypothesis removes part of the excessive freedom of assumptions in dynamic models. In deterministic models, rational expectations are equivalent to perfect foresight, so that the expected path of prices in a model is the path that, according to the model, subsequently ensues, given the expectations. Perfect foresight in monetary growth models implies instability of the inflationary process if no jumps in the price level are permitted; alternatively, if jumps in the price level can take place, perfect foresight implies there are many possible paths for prices, only one of which is stable. This saddle-point indeterminacy-instability result is similar to the well-known Hahn paradox of capital theory and raises the question of whether the unique stable path will be followed in a private economy. William Brock presents an optimizing money and growth model in which the economy follows the stable-perfect foresight path because it is utility maximizing. The types of policy actions which are consistent with the perfect foresight assumption are limited: in perfect foresight models, preannounced changes in the growth rate of money lead to changes in the inflation rate before the change in the monetary growth rate occurs.

In a stochastic model, the rational expectations assumption is that the subjective probability distributions used in decision making by private agents are the same as the probability distributions for the relevant variables implied by the model. More generally, if individuals do not have all the information used in the model, expectations are rational if they are optimal predictions based on the information available to the individual.

Rational expectations in the context of limited information by market participants have been used by Robert Lucas (1972 and 1973) to generate a short-run Phillips curve in models in which the long-run Phillips curve is vertical. In Lucas' models, participants in a given market are aware of current conditions only in that market but do know economywide conditions for previous periods. Demand in a single market may change either because of real demand shifts or because of economywide changes in nominal demand caused, say, by monetary growth. Since suppliers in a single market cannot distinguish the cause of a current disturbance in their market, they do adjust output to nominal disturbances even though they would not do so if they were informed of the cause of the disturbance. Thus, in the short run, suppliers can be fooled into increasing output by a process which also increases prices, generating a short-run Phillips curve. However, the tradeoff vanishes over time as knowledge of conditions elsewhere in the economy is obtained.

Models in which the Phillips curve is a result only of expectational errors have radical implications for policy when combined with the rational expectations assumption—essentially because the latter causes long-run results to hold in the short run. In a series of papers, Thomas Sargent and Neil Wallace show that, under rational expectations and with an expectational Phillips curve, the behavior of the economy is invariant with respect to the preannounced systematic part of a monetary policy rule since, essentially, only surprises produce a real response. It is possible for the monetary authority to affect output, at least temporarily, by concealing its actions; John Taylor uses a model in which individuals form expectations rationally, but the use of a random monetary rule enables the monetary authority to fool individuals and so affect output. It is, of course, another matter as to whether the monetary authority should want to affect output. More generally, Lucas (1973) uses rational expectations as the basis for a forceful restatement of the position that the use of existing econometric models for policy evaluation is dangerous since the parameters of such models can be expected to change with policy.

Although the rational expectations hypothesis provides a consistent explanation of some cyclical phenomena, it arouses a number of strong reactions. One reaction is that it is absurd to assume individuals can make the necessary calculations since most economists still cannot do so; however, individuals and firms do read newspapers and buy consulting services, and their expectations are influenced by model predictions. The rational expectations assumption *is* excessively strong since it ignores uncertainty over model selection, but it is a more persuasive starting point than the assumption that a rule of thumb is used for expectations formation which is independent of the stochastic properties of the time path of the variable about which expectations are formed. A second reaction is not so much to rational expectations as to expectational Phillips curves; it is argued that there are real reasons for short-run price inflexibility which produce a short-run Phillips curve and that the policy implications of rational expectations mentioned in the preceding paragraph are accordingly incorrect. While I am in sympathy with this view, I think it fair to say that a convincing model underlying the argument has yet to be produced. A third reaction is to the perfect foresight models and the restrictive role for policy in them; while perfect foresight is an unattractive assumption the cure is not necessarily to use nonrational expectations assumptions, but instead to use nondeterministic models.

V. Conclusions

Summary conclusions on each of the four branches of the literature surveyed here and some comments on gaps which need filling are presented in the preceding sections. There are other areas in which theoretical research is required and is taking place: existing models of money demand are chronically unable to explain the volume of money holding even though they do successfully predict the direction of interest rate changes on demand; advances in the theory of finance are being incorporated into macro models; the effects of indexing on the operation of financial markets and economic stability are being studied; monetary theory is being incorporated into trade theory. However, it is clear from sections II–IV of this paper that many of the major outstanding questions in monetary theory, and macroeconomics more generally, are related to the Phillips curve (or the famous missing equation) and concern the short-run dynamics and costs of inflation and unemployment. It is in this area of dynamics that most progress has been made in the past quarter century, and it is in this area that progress is most needed.

Empirical Monetary Macroeconomics: What Have We Learned in the Last 25 Years?

By W. C. BRAINARD AND R. N. COOPER*

Monetary economics conveys the impression of great disagreement within the economics profession, and indeed the professional debates have often been heated. But behind the debates over policy there is a great deal of consensus on the importance of monetary variables for the working of national economies and on the mechanisms through which they exert their influence. The title of this session reminds us that twenty-five years ago this was not so. When Howard Ellis wrote "The Rediscovery of Money," the postwar revival had just begun. There was general skepticism about the ability of monetary policy to influence the economy, and the Oxford surveys were widely cited as the empirical basis for disbelief in the effect of monetary policy on investment. Despite the emergence in the intervening years of wide agreement about the importance of monetary policy, the empirical basis for many of our beliefs, and a fortiori for distinguishing among our differences, has remained weak.

In casually accepting our present assignment, we failed to appreciate just how complex the question posed in the title is. This is true even when the subject is confined, as here, to the monetary economics of the business cycle, leaving aside both microeconomic and steady-state growth considerations. What does it mean to say we have "learned" something? And to whom does the "we" refer?

We interpret the first question to refer to how much we now know, compared with twenty five years ago, about managing the economy with instruments of monetary policy. Empirical knowledge is embodied in reliable quantitative economic relationships. This perspective does not, of course, encompass all of monetary economics, but it does encompass most of the professionally salient issues.

Who are "we"? There are often marked differences in the "knowledge" embodied in the most advanced work, in conventional professional wisdom, in ordinary textbooks, and in monetary officials. To what group should we apply our test of knowledge? Certain individuals are at the forefront of the profession, some with a pack of followers, others in splendid isolation; some are recognized at once, others with a short lag, and still others drop into oblivion to be rediscovered much later. For example, Irving Fisher explored what we now know as the Phillips curve in 1926 with an econometric sophistication which rivals all but the most recent work in the area. Diligent search can usually find a precursor to any idea. As Roberta Wohlstetter discovered in her study of the Pearl Harbor attack, the problem is not the inadequacy of information; rather, it is to separate the true signal from the noise. In an active intellectual discipline, this is always done with much greater clarity long after discoveries are first made. For this reason, while it might seem most appropriate to concentrate our attention

---

* Yale University.

on the most advanced work, it is neither easy nor fully appropriate to do so, since we may not even know where the true frontiers of the subject are at the present time.

In some respects, monetary economics as a whole was just being "rediscovered" as an important field in the late 1940's and a twenty-five year survey starts near a low point. The outpouring of empirical work in monetary economics during the past two decades—and especially during the past decade—has been vast. A simple bibliography of professional articles alone would exhaust the space allotted to us. We must be highly selective and, therefore perforce, somewhat impressionistic. We first present some quantitative information on professional articles on empirical monetary economics in the late 1940's and in the early 1970's, along with a brief characterization of these articles. We then discuss the chain of monetary influence as embodied in empirical macro models of the *U.S.* economy. Finally, based on these comparisons and on an impressionistic sampling of other literature, we offer some generalizations about improvements in our knowledge and about areas where our ignorance remains great.

We are concerned mainly with the endpoints of our period. Limitations of space prevent consideration of many important milestones within the period, such as Gurley-Shaw, the Radcliffe Report, the Commission on Money and Credit, Friedman-Schwartz.

I. Quantitative Assessment

One measure of the relative importance and the character of empirical work in monetary economics now as compared to the late 1940's can be obtained by surveying articles in the professional journals. We have counted the articles (including notes and replies) on monetary economics in four journals, representative of the best current research by the profession and published at both the beginning and end of our period: the *American Economic Review*, the *Journal of Political Economy*, the *Quarterly Journal of Economics*, and the *Review of Economics and Statistics*. The results confirm the general impression of a great increase in work on monetary economics: in the period 1948–50 there were twenty-six articles in the four journals, of which fifteen were theoretical and eleven were empirical. In the period 1970–72, there were eighty-seven articles on monetary economics, of which fifty-one were theoretical and thirty-six were empirical. This undoubtedly understates the growth since at least one major journal, devoted entirely to research in the monetary area, was created during this period, the *Journal of Money, Credit and Banking*. Thus, there was a sharp increase in both theoretical and empirical work on monetary economics. Moreover, there was a marked shift in the character of the empirical articles: in the earlier period three were historical-analytical and eight involved graphical analysis of two variables.[1] None contained regressions. In the latter period, by contrast, thirty-three involved regression analysis, two involved simulations, and one contained only graphical analysis.[2]

This great increase in quantitative empirical work, of course, reflects the increased availability of better data and of high speed computers permitting their analysis, but also greater appreciation of the intrinsic complexity of monetary relationships, calling for multivariate and simultaneous equation analysis.

---

[1] Examples of empirical articles from 1948–50 are E. Marcus, Kenneth Roose, James Tobin, Clark Warburton, and Charles Whittlesey.

[2] These findings may have reflected in part a change in editorial policy regarding regressions. But regression analysis was used in other areas of economics, especially in the *Review of Economics and Statistics*. And *Econometrica* also contained no regression analysis on monetary economics during 1948–50.

In certain respects, the sharp growth in quantification itself represents a substantial gain. It compels more exact thought, both as regards the relationships among variables and as regards the variables themselves. Theoretical formulations can speak of "the" interest rate and "the" money supply, for example, but the quantifier must choose precisely what interest rate and what definition of the money supply he is going to use. This is a useful discipline, if only to indicate that our theoretical concepts are not quite as operationally sharp as we would like them to be. Second, quantification permits some assessment of the quantitative importance of the variables in question; effects of negligible practical importance often command disproportionate theoretical attention. On the other hand, a preoccupation with quantification may result in neglect of important but not easily measured variables. And quantification is itself no assurance against misspecification.

One of the most dramatic changes during the period is the increase in the number of working econometric models purporting to describe the behavior of the *U.S.* economy. No less than eleven models are participating in the National Bureau of Economic Research-National Science Foundation (*NBER-NSF*) continuing seminar on the comparison of econometric models, and since 1970 at least four different models have been used for regular quarterly forecasts one to five quarters ahead. Models of this type have the advantage of embodying concrete quantitative information about empirical linkages in the economy.

In 1950, econometric models were in their infancy. Few thought of them as a practical tool for forecasting the economy or the impact of policy; rather the concern was with the extent to which a model could capture the salient features of the economy and its cyclical behavior, and with problems of econometric methodology. Nevertheless, comparison of the difference in the treatment of the monetary sector in these models and their modern counterparts gives dramatic testimony to the cycle in the profession's perception of the importance of monetary factors in the determination of income and prices. As reflected in the models, the recovery of money from the Great Depression was protracted. When Marc Nerlove did his survey of the six models estimated from postwar data in 1966, for example, only two had more than two endogenous financial variables, and three had no monetary sector at all. This contrasts sharply with the remarkable model by Jan Tinbergen (1939), which contains an elaborate monetary sector. By the end of the period most of the models included a substantial monetary sector. Perhaps the most sophisticated and most widely emulated is the financial sector of the MIT-PENN-SSRC (*MPS*) model. In it monetary policy has powerful effects on income and works through a rich and complicated set of linkages. While it has been the subject of criticism by monetarists and nonmonetarists alike, it has gone a long way towards resolving some of their differences.

At the same time that structural models were in the process of reintroducing money, there was an effort, stimulated by Milton Friedman and David Meiselman, to determine whether simple single-equation Keynesian or monetarist models provide a better explanation of money income. In retrospect, it appears clear that it is not possible to discriminate between competing macro models simply on the basis of in-sample fit. Given the highly serially and cross-correlated nature of economic time series, the range of choice of variables for use in any model, and the flexibility in the specification of lags, marvelous fits of historic data can be obtained by models with widely different implications for the behavior of the economy and its response to policy. Out-of-sample forecasts provide a better test, but it appears difficult to discriminate between the simple Keynesian and monetarist models on this basis. Although out-of-sample forecasts do not provide a clear verdict on which of these single-equation models predicts best, they do show persuasively that these models, taken as a class or individually, cannot compete successfully with the more complicated models, structural or otherwise, nor for that matter with the median of judgmental forecasts. Today, most economists would probably agree with William Poole and Elinda Kornblith when they say (p. 915), "neither the simple Keynesian nor the simple quantity-theory models provide an adequate understanding of business cycle fluctuations . . . there simply is not much empirical content in the single-equation approach as employed in the studies examined here."

Given the fact that economic data do not distinguish sharply between competing views, the plausibility of theoretical explanation will continue to bear heavy weight in distinguishing among alternative hypotheses as well as in guiding our exploration of the data. For that reason, students of monetary economics will want to know how money works. They will want to know how specific components of demand are connected to money markets and the accuracy of predictions about the behavior of the links in that causal chain.

II. Channels of Monetary Policy

Earlier monetary writings are very rich in their verbal treatment of the influence of monetary variables on economic activity and at a general level our knowledge has not advanced beyond them. No one has discovered a brand new channel of influence, and indeed some of the monetary effects identified earlier, such as the importance of business and consumer expectations, or "confidence," have not yet been satisfactorily incorporated into quantitative models.

We will organize our discussion of linkages from the perspective of the policymaker. From his view, the instruments of policy are directly controlled. Thus, the direction of economic causation runs from his instruments to the rest of the economy. A simplified rendition of the chain of influence is as follows:

$$\begin{tikzcd}
& & & & P \\
CB \arrow[r, "(1)"'] & H \arrow[r, "(2)"'] & MM \arrow[r, "(3)"'] & Y \arrow[ur, "(4a)"] \arrow[dr, "(4b)"'] & \\
& & & & Q
\end{tikzcd}$$

where CB = the central bank, H = high-powered money, MM = money markets, Y = money income, Q = the volume of output, and P = the overall price level. The important empirical questions concern the magnitude and the reliability of each linkage. From the econometrician's point of view, of course, policy however measured is unlikely to be exogenous. This fact creates problems of estimation and interpretation of both reduced form and structural equations. Similarly, the influence of exogenous variables and the feedback from price and output greatly complicate the estimation of this chain.

In this scheme, what is the instrument of control? Taken literally, the central bank controls its portfolio of assets, the discount rate, reserve requirements, and other regulations which restrict and influence the behavior of banks and other institutions. But effective control may extend much further into the private realm. What effective control is, of course, depends upon the objectives of policy and the horizon in question.

Early discussion tended to focus on the quantity of currency plus demand deposits as the important element in MM. The central bank controlled this quantity, which was tied directly to Y by a velocity or demand for money function. Recently a number of studies suggest that control of M_1 over periods as short as a month may be difficult. Given other, longer lags in the system, it does not seem to us that this possibility is itself a cause for alarm. It is also apparent that over a cycle in economic activity there is a difference between controlling H and controlling money, even if money is defined narrowly. Earlier generations of students were trained in increasingly elaborate mechanics of the money multiplier, which tied the volume of bank deposit liabilities directly to the supply of high-powered money. The ability of the banking system to affect this multiplier by borrowing or altering excess reserves has long been recognized.[3] But while this slippage may decrease the magnitude of response to changes in H, it is not likely to be so rapid or so dramatic as to prevent control of a particular M over the medium term.

Over longer periods, postwar experience with the development of the federal funds market, the emergence of certificates of deposit, and the development of ties between American banks and the Eurodollar market demonstrate how institutional adaptation to profit-making opportunities and regulation may change the relationship between H and money, no matter how defined. Such endogenous institutional changes suggest that it may be difficult to specify any simple rule for monetary policy applicable to the long run.

It would be possible to tighten the linkage between H and a particular M by implementation of proposals such as that for 100 percent money (Lloyd Mints). However, the growth during the period in bank liabilities other than demand deposits, in deposit liabilities of financial intermediaries, and in other near monies makes clear the difficulty of settling on any single definition of money for policy purposes. Improving control over one variable is likely to increase slippages elsewhere in the system.

While there is still much disagreement about the best way to describe empirically the third linkage, connecting money markets and national output, monetary economists have come a long way towards agreement about general outline of the process. Such diverse writers as Tobin, Allan Meltzer and Karl Brunner, Friedman, and Franco Modigliani stress the importance of recognizing that a broad spectrum of assets and commodities are affected by monetary disturbances, and of distinguishing between the rates of interest, nominal or real, on financial assets and the required rate of return on capital or durable goods. This latter point, which can be found in Tinbergen but was neglected in virtually all models until the *MPS*, can be formulated in a variety of superficially different ways. According to all these authors, discrepancies between the required rate on physical assets and their marginal productivities, or equivalently, between the current valuation of these goods and their replacement costs, stimulate or discourage their production.

One important implication of this more complex view of the *modus operandi* of monetary policy is that the second and third linkages fuse, and changes in policy can influence Y without necessarily going through any particular monetary aggregate.

Traditional concern with the variability of "velocity" involves the third linkage. At a theoretical level it was long assumed that the essential issue was the interest elasticity of the demand for money, an empirical issue on which the relative effectiveness of monetary and fiscal policy was assumed to hinge. In models which incorporate a wide variety of financial markets, the role played by the demand for any particular definition of money is displaced by the demand for high-powered money, H. The now widely accepted view that the demand for money depends on interest rates then becomes only one reason for some elasticity in the demand for H.

---

[3] It is interesting to note that Tinbergen's model includes an explanation of bank demand for net free reserves not unlike that studied by A. J. Meigs and C. Morrison in the late 1960's and embodied in the *MPS* model thirty years later.

It is not difficult to construct models of financial and commodity markets which honor the distinctions among real and financial assets and rates, but the simultaneous adjustment of financial markets and imperfections in markets for existing physical assets make it difficult to utilize them econometrically. The builders of the *MPS* model, for example, did not find it possible to identify separate supply and demand equations for most of the wide range of financial assets represented in the model. Instead, they rely heavily on a "term structure" equation to tie the markets together. Among other things, this simplifying assumption ignores the cumulative impact of net government borrowing on the relative supplies of bonds, capital, and other assets. As a result, the effect of government debt on the required rates of return on capital cannot be captured in the model. This assumption also restricts the ability of monetary disturbances to affect the demand for real assets without going through a long chain of financial markets. This weakness is partially remedied in the recent Bosworth-Duesenberry model of flow of funds and other models currently under construction, which include a complete set of supply and demand equations for financial assets; but it seems unlikely that such models will be reliably estimated from time series data alone.

During the period under discussion an enormous amount of quantitative empirical work has been done on various sectors of the economy. This work suggests that monetary variables have a substantial effect on expenditures. Interest rates appear to have an important influence on expenditures for plant and equipment and for purchases by state and local governments. In the early 1950's much weight was put on the "availability" of funds, and we know that this is especially important today in influencing housing and perhaps other expenditures as well.

Another linkage between financial markets and expenditures arises from interest-induced changes in asset prices and from changes in the real value of financial wealth in terms of goods and services. In the *MPS* model, for example, interest rates can have a very large effect on stock market valuations and, even with small marginal propensities to consume capital gains, are responsible for making consumption very responsive to monetary policy. The magnitudes of these effects are open to question. We do not yet understand how much is permanent and how much is regarded by wealth holders as representing temporary vicissitudes in monetary policy, with negligible influence on spending.

There has been much debate over the fourth linkage, with Keynesians emphasizing the impact of increased money income on real output and monetarists emphasizing the impact on prices. Both schools of thought have acknowledged that both effects are generally present in the short run, and the discussion has come to focus on the relative magnitudes of the short-run effects and on whether any effect on output endures in the long run. Of the linkages identified above, this one is the least well understood; forecasting errors on price changes are large, we have virtually no policy instruments to influence the division between Q and P, and we have virtually no dynamic adjustment theory to indicate what division to expect at any moment of time. What empirical evidence we have suggests that we can forecast Q better than Y. That is, in the short run prices are influenced by factors not well captured by the models. Furthermore, the effect of changes in demand on prices appears to be slow.

The above chain of influence assumes, as most economists do, that the central bank is an autonomous agent and that it can determine H, high-powered money. Both assumptions are subject to question, at least under some important circumstances.

In democratic societies, central bank behavior is really endogenous to a model of the political process, so we need to close the circle of causation with a fifth linkage, running from P and Q to CB. This is more the domain of political scientists than of economists, but, as noted above, it affects the descriptive value of macro models and introduces simultaneous equation bias into econometric estimates. Moreover, it suggests that economists should not pretend that central banks can pursue freely their own preferences or those of their advisers, and should direct greater professional attention to enlarging and improving the range of instruments, nonmonetary as well as monetary, for influencing target variables.

The extent to which central banks can influence high-powered money can also be questioned. Work on the monetary approach to the balance of payments has reversed the whole chain of influence, at least for a small country with a fixed exchange rate. Q is determined by real factors, and P is determined by the exchange rate and the world price level. These together determine Y, which determines the demand for money, which in turn influences public behavior to assure adequate supply, if not directly from the central bank, then through the balance of payments. Attempts by the central bank to supply more or less than the desired amount of money will simply result in deficits or surpluses in the balance of payments. David Hume has been rediscovered, and the money supply becomes completely endogenous.

This line of reasoning is less applicable to a large country, to a country whose currency is a reserve currency, and to a world of flexible exchange rates. But it does not become wholly inapplicable under any of these circumstances as they are likely to obtain in reality. Moreover, the use of a national currency as an international currency in private transactions raises serious questions about operational meaning of M: are *foreign*-held dollar balances related to money income in the United States? Or in the country of the holder? Or both? The substantial size of the Eurocurrency market gives rise to a host of measurement problems which in turn reflect some looseness in our concepts of money.

III. Predictive Accuracy

Better knowledge should lead to better forecasts of the economy. Forecasting out-of-sample offers one of the few genuine tests of whether or not our knowledge of reality has improved and of the influence of policy actions on the economy. In fact, there seems to have been a substantial improvement in our ability to forecast short-term economic developments. The median forecast in the early 1950's had a mean error of about 2 percent in forecasting nominal GNP four quarters ahead (Victor Zarnowitz). Formal macroeconomic models had a mean error of only about 1 percent in such forecasts in the early 1970's (S. McNess). It is also clear, however, that forecasting performance is not a powerful tool for testing alternative model specifications. Although the more complicated models appear to have overtaken judgmental forecasts and on average outperform single-equation or extrapolative forecasts, it is not clear how important elaborate specification of structure is in achieving this improvement. A substantial amount of judgment is typically used in the operation of the more complicated models. Even so, Ray Fair's relatively simple 20-equation model, containing very little structure and used mechanically, performs nearly as well as the more complicated models and appears to outperform them when they are also used mechanically.

These short-term out-of-sample forecasts on aggregate economic variables do not test the model's ability to predict the response of the economy to major changes in policy. In the absence of experiments in policy, our only guide to performance in this regard is the ability of the models to predict well the large number of endogenous variables which transmit the effects of policy actions to the target variables. Unfortunately the record so far is not outstanding (Charles R. Nelson).

One of the problems which plagues macro-model builders is the difficulty of distinguishing adjustment lags, expectations, and serial correlation of errors. These phenomena lead to a high degree of autocorrelation in many economic series, which is one of the reasons that naive autoregressive predictions do so well in short-term forecasting. They presumably are also the reason that it is typically quite difficult to pass tests of causation which call for strong relationships between movements in economic variables purified of autocorrelation. (See Christopher A. Sims 1972 and C. W. J. Granger.)

Treatment of lags in the early models was very primitive. Part of this reflected the absence of data on a more frequent than annual basis, and it seems clear that annual data do not provide very much information about the lags in most economic relationships. Quarterly models, starting with James Duesenberry, Otto Eckstein, and Gary Fromm, provide a substantial improvement in this respect, but confidence in the reliability of estimated lag structures is still quite low. In addition to all the other difficulties in estimating lag structures, recent work by Sims (1971) and J. Geweke suggests that, due to "stroboscopic" effects, estimation of continuous processes by the use of discrete time observations may yield a fitted lag structure very different from the true lag structure.

A closely related weakness in the models—and in our empirical knowledge generally—concerns the formation and the alteration of expectations. The frequent and convenient use of adaptive expectations implicitly assumes nonrational behavior on the part of the economic actors. Over time, rational expectations will take into account the actions of the policymakers, and this, in turn, can lead to an alteration of the structure of the economy itself, rendering any given model obsolete. Policy-induced institutional change, which has been very important in the *U.S.* financial sector over the past two decades, is one example of this; regulations create incentives to evade them. Another example is the alleged decline in money illusion and a tendency for investors and savers alike to respond to real rather than nominal interest rates. Under the circumstances of evasive changes in expectations and in economic structure, policymakers might well find that an optimizing strategy would involve deliberately introducing some ambiguity—for example, through randomizing—into their countercyclical actions. Close students of monetary policy might even say that the Federal Reserve has been using this principle from game theory all along.

DISCUSSION

MILTON FRIEDMAN, University of Chicago: The papers by Stanley Fischer and by William Brainard and Richard Cooper are excellent summaries of recent work in the respective areas each surveys and I have only minor quarrels with either paper. Yet neither seems to me to give a satisfactory answer to the question posed for this session. The trees almost completely obscure the forest.

Would it be apparent to anyone reading these papers that twenty-five years ago the bulk of professional economists regarded "money" as simply a five letter word describing an utterly passive magnitude that responded to other economic forces but had negligible independent influence; that they took it for granted that inflation and unemployment alike could be relegated to a benighted historical past, if only policyholders could be persuaded to adopt the new Keynesian insights about fiscal policy; that the only role assigned to monetary policy in this happy scenario was to keep interest rates low; and that the quantity theory was of interest only to historians?

The past twenty-five years have seen a revolution in professional thinking. The revolution is well described in the title of this session as a "rediscovery," for indeed, as I shall note shortly, it is far harder to specify what "we"—meaning the profession of economics—have learned in the past two hundred years than what we have learned in the past twenty-five years.

To try to delineate the forest, the major components of that rediscovery have been:

1) The interest rate is the price of credit, not of money. The price of money is the inverse of the price level. Monetary authorities can control directly the quantity of money and thereby determine the long-term rate of inflation.
2) Nominal interest rates must be sharply distinguished from real interest rates. One implication is that while more rapid monetary growth may lower interest rates in the short run, it will raise them in the long run as it produces inflation which is embedded in interest rates.
3) The price level and inflation are monetary phenomena, not institutionally determined data to be analyzed by psychologists and industrial relations and industrial organization specialists.
4) There is no stable Phillips curve tradeoff. This is the empirical counterpart of the critical role in monetary theory today of the distinction between "anticipated" and "unanticipated" magnitudes.

I wish I could say that this rediscovery reflects the influence of the scientific work in monetary theory and empirical analysis that was initiated by a small group of dissenters from the prevailing orthodoxy twenty-five years ago, a trickle that has since grown to a veritable flood, as Brainard and Cooper point out. But that is not the case. The rediscovery reflects primarily the impact of experience. How can any teacher of elementary economics today stand in front of a class and begin his exposition of what is inelegantly called "macroeconomics" with the statement: "throughout this course we shall treat the price level as fixed"? Yet that is what essentially every teacher of elementary economics told his students twenty-five years ago. Or how can he, with a straight face, draw a liquidity preference diagram with nominal quantity of money on one axis and nominal interest rate on the other and explain to his students in these terms why the prime interest rate today is in double-digits? Double-digit inflation and double-digit interest rates, not the elegance of theoretical reasoning or the overwhelming persuasiveness of serried masses of statistics massaged through modern computers, explain the rediscovery of money.

That it is a "rediscovery" is easily demonstrated. Re the interest rate and the quantity of money, David Hume wrote more than two hundred years ago, "Lowness of interest is generally ascribed to plenty of money [and so it was twenty-five years ago]. But money, however plentiful, has no other effect, *if fixed*, than to raise the price of labour. . . . In the progress toward these changes, the augmentation [in the quantity of money] may have some influence, by exciting industry, but after the prices are settled, . . . it has no manner of influence."

Re money, inflation and employment, that is, the Phillips curve issue, listen again to Hume: "Though the high price of commodities be a necessary consequence of the increase of gold and silver, yet it follows not immediately upon that increase; but some time is required before the money circulates through the whole state. . . . At first, no alteration is perceived; by degrees the price rises, first of one commodity, then of another; till the whole at last reaches a just proportion with the new quantity of specie. . . . In my opinion, it is only in this interval or intermediate situation, between the acquisition of money and rise of prices, that the increasing quantity of gold and silver is favourable to industry. . . . From the whole of this reasoning we may conclude, that it is of no manner of consequence, with regard to the domestic happiness of a state, whether money be in a greater or less quantity. The good policy of the magistrate consists only in keeping it, if possible, still increasing; because, by that means, he keeps alive a spirit of industry in the nation. . . . There is always an interval before matters be adjusted to their new situation; and this interval is as pernicious to industry, when gold and silver are diminishing, as it is advantageous when these metals are increasing."

You can see why I say that it is far harder to answer the question, "What have we learned in the past 200 years?" than "What have we relearned in the past twenty-five years?"

As I see it, we have advanced beyond Hume in two respects only: first, we now have a more secure grasp on the quantitative magnitudes involved; second, we have gone one derivative beyond Hume.

On the first point, while we clearly have advanced, we must not overrate the advance. I was taken aback this summer in rereading William Stanley Jevons to come across the sentence in an essay first published in 1863: "An expansion of the currency occurs one or two years previous to a rise in prices." I thought I had been the one who had identified the lead of money over output and nominal income as six to nine months and over prices as two years! And there was Jevons a century ahead of me.

On the second point, Hume took it for granted, as did Irving Fisher fifty years ago, that stable prices were the norm, that generally rising or falling prices would be a departure from the norm, so would be unanticipated and so be "advantageous" or "pernicious" to industry. Today we have been forced to recognize that a changing price level—empirically, a rising price level—may be embodied in the public's expectations so that it takes an acceleration or deceleration of monetary growth to have the effects that Hume attributed to a rising or falling price level. We may soon be forced to still higher derivatives.

The need to go one derivative beyond Hume is what underlies one of the most important recent strands of monetary theory, stressed alike by Fischer and Brainard and Cooper—namely, analysis of the formation of anticipations and particularly rational expectations.

Once we recognize, as Hume did, that only unanticipated changes in the quantity of money will systematically produce a divergence between the actual rate of unemployment and the "natural" rate, the way anticipations are formed becomes a vital issue in the evaluation of monetary policy. The recent work in this area discussed by Fischer, particularly by R. Lucas and T. Sargent, brings us back to Henry Simons. As Fischer noted, if anticipations are formed rationally, no fixed policy on the part of the monetary authorities will produce a divergence between the actual and "natural" rates of unemployment. Only continuously "fooling" the public will do that. Is it not far better, along with Simons, to get instead the cooperation of the public by announcing in advance a policy and sticking to it? Though Lucas and Sargent have stated the point formally far better than it has been stated earlier, this has always been, as I see it, an essential foundation of the preference by Simons and his followers, including myself, for a fixed and announced rule of monetary policy.

The need to go to a higher derivative also underlies, I believe, the contrast referred to by Brainard and Cooper between the excellent forecasting performance of various models in predicting nominal income and their extremely poor performance in predicting the breakdown between prices and output. The change in nominal income has been linked now as in the past to the first derivative of money through a relatively stable velocity function. But the division between price and output has been linked to the higher derivatives through their effect on the division of monetary changes between anticipated and unanticipated changes.

In this connection, I may perhaps close on a somewhat more optimistic note for theory—though not for our near-term future—by disagreeing with Brainard's and Cooper's statement that "we have virtually no dynamic adjustment theory to indicate what division to expect at any moment of time" between output and price changes. I believe we have a reasonably good dynamic theory—what we lack for policy purposes is not the theory but the political capacity to use the theory effectively.

That dynamic theory—which I shall spell out oversimply, using *U.S.* quantities to make it highly specific—is little more than an expanded version of Hume's, but one that uses the quantitative knowledge that we have accumulated. At any time, the effect of monetary change depends on the public's anticipations about monetary change. Start from a hypothetical, reasonably balanced situation when monetary growth has been proceeding for some time at a constant rate so that the public in general has adjusted to that rate. *GNP* in nominal terms will then be growing at about the same percentage rate as M_2, prices at about 3.0 to 4.0 percentage points less. Let the growth rate of M_2 accelerate. For something like six months, the main effect will be that actual balances will exceed desired balances, which may temporarily depress short-term interest rates but will have little other effect. After about six to nine months, the rate of growth of nominal *GNP* will accelerate, as holders of the excess cash seek to dispose of it. The increased spending, by precisely the process Hume described, will "excite industry," as producers facing unexpectedly high nominal demands treat the increase as special to them and so seek to expand output. For a time they can do so, because their suppliers too, including laborers, take the increase in demand as special and temporary and do not alter their anticipations. This, if you will, is the temporary Keynesian phase, where output responds more quickly than prices. In its course, prices do respond, rising more rapidly than before, and interest rates stop falling and start to rise. But it takes about eighteen months after output starts to quicken—or two years after money accelerates—for the main effect to have shifted from output to prices. During this period, anticipations are changing, reflected most sensitively perhaps in interest rates, but even after prices have started to absorb the bulk of the acceleration in money, anticipations have not fully caught up. In the next year or so they will, which will force a decline in the rate of growth of output back to or below the "natural level," producing the stagflation stage.

I hasten to add, first, that this is the briefest of sketches; second, that the numerical magnitudes are based on the *U.S.* experience today and will change. In particular, the lags will shorten if the fluctuations in monetary growth continue to become more erratic, as I fear they may. But to stick my neck out, rather than shelter it, I may say that I believe we are in the early stages of an episode of roughly the kind I have described. As I read the tea leaves that emanate from the Federal Reserve—as an aside, why do they make us read tea leaves, instead of following the ancient wisdom of Simons and the new wisdom of Lucas and Sargent and telling us clearly and simply what they plan to do?—monetary growth sharply accelerated in October. If this accelerated rate continues (roughly 10 to 12 percent for M_2), the current recession will end in some six months or so, but inflation will continue to taper off under the influence of an earlier deceleration of money to something like 6 or 7 percent, but then, by say early 1976, the monetary acceleration will bring the tapering off of inflation to an end; by mid or late 1976, the rate of inflation will be back to perhaps 3 percentage points under whatever turns out to be the rate of growth to which M_2 settles down from October 1974 on. Inflation will then accelerate further until about mid-1977 when, if monetary growth has not accelerated still further, we shall be entering into the next episode of stagflation. Needless to say, the details of this scenario may be distorted or concealed by price and wage control, but not fundamentally changed.

If this scenario does develop and we end up in 1977 with 10 to 15 percent inflation and growing unemployment, it will not be because we do not have a "dynamic adjustment" theory, but because we do not have the political will to apply the knowledge we have.

FRANCO MODIGLIANI, Massachusetts Institute of Technology: We must be thankful to Stanley Fischer for his excellent survey of major recent developments in monetary theory, and to William C. Brainard and Richard N. Cooper (hereafter B–C) for tackling, with a good measure of success, the difficult task of surveying developments in our understanding of the role of money and monetary policy in the determination of real and money output. Still, I am inclined to agree with Milton Friedman that the two papers have failed to convey fully the dramatic revaluation of the importance of money which has occurred in the economic profession since the Second World War. At the same time, I differ with him on two main issues: (1) I disagree with the view that the revaluation resulted primarily from the rediscovery of old truths, and (2) I have serious questions about his list of propositions rediscovered.

Dealing first with (2), I would hope that economists have *not* rediscovered half-truths, such as that the price of money is the reciprocal of the price level, but continue instead to remember that money has as many prices as there are commodities, current and future, for which it can be exchanged. Again, while agreeing that the recognition of real rates as a determinant of real and financial investment behavior is an important rediscovery, I suggest that it has occurred simply because inflation has made the distinction between money and real rates become empirically important. At the same time, I would stress the equally important discovery (and not rediscovery) that because of institutional forces—such as the extensive reliance on level-payment mortgages to finance acquisition of dwellings and the reliance on financial intermediaries to supply those mortgages, subject to ceilings on nominal rates—investment behavior can be affected also by nominal interest rates. This proposition is well illustrated by this year's collapse in the housing market.

Finally, I hope and wish that no one is rediscovering that inflation is money determined, because in my view it is again at best a highly oversimplified and misleading half-truth. It is agreed that a high rate of inflation could not long be sustained without a sufficiently fast rate of growth of M and that a sustained high rate of growth of M (relative to the growth trend of output) could not fail to be accompanied, eventually, by a high rate of inflation; but this is quite different from saying that every instance of inflation is caused by excessive money growth. The first appearance of inflationary developments is typically the result of an excess of demand relative to capacity, and this may be due either to overexpansive *monetary* or *fiscal policy*. Indeed, when I look at the recent inflationary experience going back to 1966, I find it hard to decide whether the prize for misbehavior should go to our fiscal or to our monetary policymakers! However, an inflationary development can also be due to exogenous cost-push, although in the case of the United States this factor has seldom played a significant role before 1973–74.

If the excess demand is maintained, then the inflation will continue, possibly at an accelerating rate, but it is correct to say that it is money determined only if it is maintained through an overexpansionary monetary policy. On the other hand, once the inflationary process gets started—whether through excessive demand or exogenous cost-push—it will take a long time to die down, even after the excess demand is eliminated. The reasons for this long lag in the response of wages and prices to demand conditions have become fairly well understood thanks to recent developments in the analysis of the mechanism of wage and price determination (search theory of the labor markets, oligopolistic markup theory), although for lack of space these developments were largely ignored or underplayed in the two survey papers. In this phase, the inflation is no longer due to excess demand-pull, but rather to what may be labeled endogenous cost-push and is clearly not money determined. This syndrome is again well exemplified by the current situation in which a severely overrestrictive monetary policy early in the year reduced demand way below capacity with unemployment around 7 percent and yet inflation continued at a two-digit rate. In this situation, in order to maintain demand and employment at a level generating enough slack to insure the gradual elimination of the inflation, *but no more*, it may be necessary for M to rise at a fairly fast clip. But it would be wrong to regard such a fast rise as the cause of the inflation, and more nearly correct to regard it as the consequence of the endogenous cost-push process.

This point might be elucidated by recourse to a parallel which I have used before. Consider the situation of a car being driven on a flat road with a posted speed limit by a hurried driver who is both law abiding and bent on conserving gas. His optimum policy is to go at the speed limit. There is some position of the gas pedal which will result in this speed. If, by error, the driver pushes the pedal beyond this "warranted" position, the car will exceed the speed limit—the analogue of demand-pull. The correct response is to reduce the pressure on the pedal at least back to the warranted position, but not to use the brake as this would be wasteful of gas. But even after the pedal is returned to the proper position, the car will continue for a while to exceed the speed limit—the analogue of endogenous cost-push—though it will eventually get back on course. And since the wheels are connected with the motor, while the car is slowing down the motor will be running too fast; but it is the wheels that push the motor, not the motor that pushes the wheels.

Turning now to the other area of disagreement, I share B–C's view that the revaluation of the role of money reflects not rediscovery, but rather the notable strides we have made in peering into the monetarists' "black box" and understanding the complex mechanisms that link the tools of monetary policy to aggregate real output, prices, and money output. Since everybody here has felt free to choose his own historical span of comparison—Fischer 10 years, Friedman 200—I may perhaps be allowed to go back 30 years to my 1944 *Econometrica* article on liquidity preference and the theory of interest and money. There are primarily two areas in which I note an enormous improvement in our understanding between that article and the present state of the art as evidenced, for instance, by the theory and empirical estimates embodied in the MIT-PENN-SSRC (*MPS*) model. The first is that of the wage-price mechanism, to which I have already referred. In the 1944 article, the wage was partly exogenous, partly in the nature of a ratchet, while the price level was determined by money income and a Marshallian competitive supply function, implying a counterfactual monotonic positive association between real wages and rate of unemployment. The *MPS* model of oligopolistic markup on minimum long-run average cost is theoretically consistent with and can account far better for the observed real wage behavior. It also implies—in contrast to some monetarists' views which even B–C seem to have implicitly embraced—that a change in money can in general affect prices and money income only by *first* affecting real output.

The second area of improvement is the transmission mechanism through which M affects real demand. In the original article, this mechanism consisted in hypothesizing that *the* money interest rates affected net investment, but with no clear notion of the underlying relation between stocks and flows.

The *MPS*, by contrast, includes a number of different mechanisms for different components of investments, and they are generally clearly spelled out. They include the James Tobin and D. Foley-M. Sidrauski putty-putty model summarized by B–C, as well as the Charles Bishoff putty-clay model, in which the cost of capital determines the capital intensity of gross additions to capacity. Furthermore, just about every component of aggregate demand (except exports and inventory investment) responds to interest rates. In particular, consumption responds through the effect on wealth of capital gains and losses due to changes in capitalization rates. But note that, despite this multiplicity of channels, the *MPS* would probably still be viewed as a nonmonetarists' model because, as in the 1944 model, money does not affect demand directly, but only through the vehicle of the family of interest and capitalization rates.

Having indicated the major areas of progress, I should mention two major aspects of the linkage mechanisms which are in great need of further development. One, stressed also by B–C, is the modeling of expectations. The other is the modeling of credit rationing (which may not be too important for the United States, but is central in many other systems).

Let me conclude by noting that the revaluation of the role of money has also resulted in a notable reduction in the cleavage of views concerning the importance and workings of money—largely, but not entirely, through the nonmonetarists moving toward the monetarists. Indeed, there is reason to believe that at present monetarists and nonmonetarists largely agree, at least qualitatively, about both the *short-* and *long-run* effects of monetary and fiscal policy. But this agreement may be somewhat misleading. For in the monetarists' view, the *long run* is around the corner and, therefore, what happens in the fleeting short run is of little relevance. By contrast, for the nonmonetarists it is the long run which is irrelevant because it is far away, and the short-run response is the only one that matters. It is this difference—plus a related difference in assessing the quantitative impact on demand of changes in exogenous variables other than monetary (and fiscal) ones—which, despite broad agreement of principle, would still lead, say, Friedman and myself to advocate much of the time, including right now, very different monetary and fiscal policies.

A CRITICAL LOOK AT THE KEYNESIAN MODEL: THEORY AND APPLICATION

The Coordination of Economic Activities: A Keynesian Perspective

By Robert Clower and Axel Leijonhufvud*

Almost four decades have elapsed since the publication of Keynes's *General Theory of Employment, Interest and Money*. In the interim we have learned, or at least we have been told, a great deal about "what Keynes said"—and also about "what Keynes meant," "what Keynes *really* meant," and, most recently, "what Keynes really meant, *really*." Still the debate continues. If past experience is any guide, indeed, numerous questions about Keynes's theory—including some of considerable intellectual and historical interest—will never be settled. Rather than add further tidbits to what looks suspiciously like an infinite regress, therefore, we propose to address ourselves on this occasion to the other aspect of the Keynesian debate that is mentioned in the title of this session: the model, or rather family of models, that economists have developed in response to the stimulus of Keynes's great work—"*IS-LM*, and all that."

What does "A Critical Look at the Keynesian Model" reveal? It seems to us that what it reveals most clearly is that *the Keynesian model produces useful and sensible conclusions only in such measure as the user of the model is a good economist.* After all, the basic textbook model imposes next to no constraints on what may be argued from it; worse yet, it is open to *ad hoc* modification and common sense extension in numerous directions at the whim of its user. As a consequence, virtually any bundle of policy measures may be advocated in "Keynesian" language and, in recent years, almost all policy discussions have been couched in just such terms. To state the case succinctly, the Keynesian model imposes virtually no analytical discipline upon its users and thereby grants them essentially unrestricted analytical license. So it is not surprising that the debate over Keynes's contribution, and over the extent to which the latter-day Keynesian model preserves it, should continue. But there is another and even more fundamental reason why the debate continues, namely, we have yet to resolve the central question posed by Keynes's assault on received doctrine: Is the *existing* economic system, in any *significant* sense, self-adjusting?

The standard Keynesian model does not address this central question. It merely leaves room for us to analyze concrete problems under all sorts of alternative presumptions about what the answer might be, e.g., that the private economy never shows any endogenous tendency to return to equilibrium, or that it always tends promptly to restore itself to equilibrium following any disturbance. Moreover, the standard model hardly allows us even to frame the central question in a manner that would direct research onto a promising track. The comparative

---

* University of California at Los Angeles.

statics of *IS-LM* constructions has a well-demonstrated capacity for converting questions about adjustment performance (or, if you will, stability) into questions about sundry elasticities in the minds of economists.

These observations do not exhaust what might be said about the Keynesian model's capacity for mischief. But the point is simply that, in our judgment, the standard model is incapable of development in the directions to which the central question requires that we turn our attention. In effect, if we wish to say anything worthwhile about the central question, we must start by averting our eyes from the Keynesian model. Where do we proceed from there?

As of the present time, it appears to us that the question posed by Keynes remains unanswered largely because of the continued failure of economists to provide a coherent account of the manner in which production, consumption, and trading activities of individual economic agents are coordinated in theoretical economic systems that bear a family resemblance to economies of actual record. If this surmise is correct, then what is called for now is either a radical reformulation of existing analytical paradigms or—as would seem clearly preferable from almost any point of view—a fresh interpretation of established ideas. We shall pursue the second of these alternatives, although this procedure is calculated to supply less grist for existing analytical mills than food for further thought.

To provide an alternative frame for macro theory capable of addressing the coordination question is a formidable task that is unlikely to be solved except by the concerted efforts of many workers. It is also necessarily a long-run task. (Perhaps that is why it never gets done—so many macroeconomists follow Keynes in being almost equally responsive to the pressure of immediate policy issues and to their own long-run mortality.) But it seems quite clear to us where we have to start. A theory capable of describing system behavior as a temporal process, in or out of equilibrium, requires a prior account of *how trade is organized* in the system. Equilibrium, steady-state theory has managed pretty well without such an account. Macroeconomic theory cannot do so. Microeconomic theories of how business and household units behave—of how production and consumption decisions are made—when the system is *not* in equilibrium will have to be predicated on some such account. How we conceptualize the organization of trade, therefore, is a question with priority over numerous other theoretical questions some of which might otherwise be of more interest and of more promise as objects of theoretical ingenuity.

I.

Our point of departure is established, general, competitive analysis as set out, for example, in Kenneth J. Arrow and F. H. Hahn's recent account of the subject. It is customary to view this body of theory as an almost literal description of an idealized economy in which the notional economic plans of individual economic agents are costlessly coordinated by a central intelligence unit—the so-called auctioneer. This neo-Walrasian conception of economic organization is sharply at variance with that of its patron saint, Leon Walras. Walras regarded his work as an attempt *partially* to characterize equilibrium states of an ongoing economic system. To suppose that Walras conceived his analysis to constitute a *complete* description even of relevant equilibrium conditions would be an egregious error—as is indicated, among other things, by his explicit denial of any such notion in Lesson 35 of the *Elements*. In effect, modern neo-Walrasian theory starts with the solution to Walras' problem, but then proceeds to ask not whether that solution is acceptable in relation to the problem considered by Walras, but rather whether we can conceive of an economy that is *completely* characterized by equilibrium relations of the kind identified by Walras! The answer to this query—the problem which, so to speak, fits Walras' solution—is, of course, affirmative; for the auctioneer model of standard theory describes just such an economy.

That this particular type of model is unsuitable for analyzing any but *virtual* disequilibria is now generally acknowledged. The question then arises: How might we best proceed to modify standard theory so that it can be used to deal explicitly, at least in principle, with *real* disequilibria? On first thought, one's natural impulse is to eliminate the auctioneer and work instead with models in which individual economic agents engage in trade on a strictly "do it yourself" basis. No doubt that is the direction in which a definitive solution to the problem of economic coordination ultimately must be sought. As of the present time, however, and probably for the near future, second thoughts counsel a more conservative procedure. Specifically, it seems preferable temporarily to continue working with models that postulate the existence of a central coordinator of trading activity, but to jettison two other assumptions of standard theory: (1) the assumption that trades take place only at prices that ensure collective consistency of individual trading plans; and (2) the assumption that trades can be negotiated and executed at no cost to individuals or society in terms either of foregone leisure or scarce resources.

Let us suppose, then, that individual agents can engage in trade only by incurring implicit or explicit search and bargaining costs that are largely independent of quantities traded. On the basis of otherwise standard assumptions, it can then be shown that individuals will abstain from consumption and amass positive inventories of tradeable goods in order to avoid prohibitively heavy costs associated with small-lot trading at frequent intervals. It can also be shown that, in the absence of arrangements that permit individuals to trade in any desired amounts at dates of their own choosing, contacts between individuals will be so costly that large potential gains from trade will remain unexploited. In these circumstances, natural forces of greed and competition might plausibly be invoked to provide a rationale for the gradual emergence of merchant traders and organized markets. In keeping with our earlier decision to stick as closely as possible to received doctrine, however, we shall proceed instead by simply postulating the establishment by social contract of a central supermarket in which individual agents may execute at will pairwise trades of any good for any other good at going rates of exchange determined by a central *trade coordinator*—the counterpart in our discussion of the familiar *deus ex machina* of the neo-Walrasian auctioneer.

So that individuals may be assumed to be able to trade at dates and in amounts of their own choosing, we suppose that the trade coordinator starts with sizable inventories of all tradeable goods. So that operating expenses may be met, and aggregate inventories adjusted over time to conform with prevailing needs of trade, we suppose further that the trade coordinator charges a fee on each transaction or, what comes to the same thing, maintains different rates of exchange on trades of x for y than on trades of y for x. Finally, we suppose that rates of exchange established by the trade coordinator are governed by two basic requirements: (1) relative rates of exchange are varied with a view to maintaining average quantities traded at levels that will ensure positive holdings of all traded commodities at virtually every point in time; and (2) differentials between buying and selling rates are varied so as to aim at a zero long-run average level of net profit. The first requirement effectively asserts that the trade negotiator is ultimately responsive to prevailing forces of excess demand; the second is a rough device to ensure that the trade negotiator acts as if he (or she) had to compete for customers with other shopkeepers.

So much for the introduction to our story, brief though it may be. All we require at this point is a coherent mental portrait—in terms of ideas that are neither entirely unfamiliar nor arrantly offensive to common sense—of an economy in which trade at other than stationary equilibrium prices may be presumed to occur more or less routinely. The model just outlined seems to meet these specifications. Accordingly, we turn now to a quick—in fact, desperately quick—discussion of the existence and stability of equilibrium, which is followed by an even faster romp through related problems associated with the identification of possible and probable sources of coordination failure.

II.

The existence of equilibria in our supermarket model can be shown to follow from essentially the same assumptions as ensure the existence of equilibria in standard theory. Broadly speaking, equilibrium requires that rates of exchange be such that average rates of purchase and consumption by individual economic agents equal average rates of production and sale for each commodity, that average inventory holdings of individual agents and of the trade coordinator be maintained at constant levels over time, and that actual inventory holdings of the coordinator be nonnegative at every point in time. The familiar zero-excess demand conditions of standard theory may be viewed as a subset of these conditions, valid in the special case where sale and purchase flows are continuous and buying and selling rate differentials are arbitrarily small. In any equilibrium situation, "notional" and "active" demands and supplies of individual agents will, of course, coincide. Subject to certain obvious and minor changes in terminology, moreover, all equilibria will be Pareto optimal.

As far as equilibrium situations are concerned, then, our supermarket model may be viewed as a straightforward generalization of standard theory. As in standard theory, so in the present model: goods are traded directly for other goods; i.e., both models portray organized barter economies. In principle, the trade coordinator might deal in all kinds of commodities—employment contracts, futures contracts, leases, rentals, loans, insurance—as well as in spot trading of physical objects. In all cases we should expect the trade coordinator to impose standard *quid pro quo* requirements—i.e., Say's Principle would be strictly observed in all trades. In the case of contracts that call for future performance of specific acts (payment of interest, rent, provision of labor services, etc.) we should expect the coordinator to impose further *accountability conditions* to guard against conscious fraud or unintentional overcommitment by individual economic agents. In the nature of the case, conditions of this sort would be costly to enforce, and all such costs would have to be borne ultimately by individual economic agents. Accordingly, we should expect trade in any but short-term and easily monitored and enforced contracts to be severely limited. In this respect, the present model stands in sharp contrast to certain versions of standard theory.

III.

Much more could be said about equilibrium properties of our model, but here the preceding rough and ready observations must suffice. Dealing next with stability, we should begin by remarking that in the context of the present model this issue cannot be discussed in terms simply of trader reactions to price changes and relative speeds of adjustment of prices. The essential question is whether the trade coordinator, acting intelligently and on the basis of information derived from past experience, can manage most of the time to maintain effective control of all inventories so that no individual economic agent is ever denied for very long the right to trade commodities that the trade coordinator normally would handle as a matter of course.

Two considerations merit special notice as factors that would tend to ensure global stability. First—and in contrast with standard theory—price variations may be presumed to be governed not by predetermined velocity coefficients, but rather by reasoned and intelligent decisions of the trade coordinator. Except in circumstances where trader reactions to price variations are both erratic and violent, therefore, it should be possible for the trade coordinator to devise some strategy of price adjustment that would ensure stability. Second—and again in contrast with standard theory—quantities actually traded by individual agents can be directly restricted by the trade coordinator in cases where price adjustments alone do not ensure effective inventory control. Thus, even in exceptional circumstances where global stability might otherwise be a serious problem, departures from equilibrium should be limited in magnitude and bounded in duration. This is not to say that what Leijonhufvud has called "corridor phenomena" are *never* of any consequence; it is merely to say that such phenomena appear to be of no consequence in a world of organized barter.

IV.

The possibility of coordination failures obviously depends directly on the stability of disequilibrium adjustment processes and upon the nature and extent of external shocks to which the system is exposed. In our supermarket model, as in standard theory, it is possible to concoct cases in which everything goes wrong; the ideas of economists extend to many things that are not dreamed of in the real world. Unless one is chronically subject to acute bouts of intellectual perversity, however, such cases are not to be taken seriously. On almost any set of reasonable assumptions about the behavior of individual agents and the trade coordinator, coordination failures should be rare or nonexistent in a world of the kind portrayed by the model considered here. To be sure, if a substantial proportion of traded commodities were highly durable capital goods, then serious problems might arise from time to time in coordinating present production of such goods with future demand for their services (i.e., future purchases of consumption goods). Such problems might be avoided if appropriate facilities existed whereby present purchasers of capital goods could contract currently for future sale of consumer goods outputs; but such facilities would be extremely costly to operate, so it would seem highly implausible to suppose that they would in fact be provided by the trade coordinator. Though we cannot rule out stock-flow complications as a possible source of coordination failures, our own impressionistic feeling—Keynes to the contrary notwithstanding—is that this complication *alone* is not of overwhelming significance. More generally, we should argue that, in a world of organized barter in which the coordination of trading activities is completely centralized, there is no serious reason to object to the classical view of economic activity as a thoroughly harmonious concert conducted by Adam Smith's invisible hand.

V.

But suppose that some rudimentary monetary and credit complications are introduced into our model. Specifically, suppose that the trade coordinator decides to decentralize exchange activities by establishing distinct trading posts for all but one commodity and designates the exceptional commodity that is tradeable at all posts as *money*. We might then imagine coordination failures to occur from time to time because individual agents develop an irrational passion for cash rather than goods and services. But such failures—commercial crises, as they might be called by a student of eighteenth and nineteenth century economic history—would surely be short-lived, for real balance effects would operate with a vengeance in this kind of commodity-money world.

Suppose next, however, that trading specialists assigned to manage various trading posts were permitted to conclude trades on the basis of book credit as well as cash. Then we should expect a significant —and perhaps predominant—proportion of all trades to be made initially on the basis of book credit, cash settlement coming later in accordance with payment rules of the kind with which we are familiar in real life. In this situation, we should have to distinguish clearly between *means of payment*, which would consist of book credit *and* cash, and *means of settlement*, which would be represented by cash alone. In situations of disequilibrium, credit means of payment could expand or contract rapidly at the discretion of individual economic agents, virtually without reference to the short-run availability of means of settlement. Inflation of money prices could occur and be sustained for some time even with a constant stock of cash, and any major interruption in cash flows (an increasingly probable occurrence as means of settlement became an ever smaller fraction of total means of payment) could produce sharp restrictions on trade. This could lead, in turn, to rapid declines in output and employment, and to consequent price deflation, resulting eventually in widespread insolvency among trade specialists as well as bankruptcy of many individual economic agents. In this kind of world, corridor phenomena might well be of major consequence; i.e., sustained and serious coordination failures might occur because insolvency of trade specialists would temporarily eliminate from the economy market homeostats that are essential for effective coordination of the notional economic plans of individual agents.

Of course the world in which we live is not like this at all. But suppose that it were. Or, more plausibly, suppose that our monetary and credit version of the supermarket model were a reasonable first approximation to the world in which we live. The implications are pretty obvious—and not at all reassuring.

VI.

Here our story must end for now, although in truth it is hardly begun—for, of course, we have yet to regain a "Keynesian perspective." The theoretical conception of the economic system with which we break off (1) lacks a central information-processing and bill-collecting agency; (2) has, instead, middlemen trying to coordinate production and consumption activities in each output market separately; (3) makes the management of stocks of inventories essential to the coordination of these activities; and (4) has the system potentially subject to commercial crises associated with expansions and contractions of the volume of bank and nonbank commercial credit. All of this might be J. S. Mill or Alfred Marshall. At most, we might stretch our claim to being "with it" to include Knut Wicksell and Ralph Hawtrey.

So what becomes of our intention to provide food for further thought? If there is such a thing as stale food for fresh thought, we can only hope that some readers will derive nourishment from noting that (a) we started from a conceptualization of economic process lodged in "modern" general equilibrium theory, (b) proceeded to complicate matters in what we dare claim to be an obviously desirable and "realistic" direction, and (c) by that route ended up with Mill!

The Keynesian Revolution Reconsidered

By ROBERT EISNER*

It all seemed so simple once. A new generation of economists, nurtured "in the new ideas," had less difficulty "in escaping from the old ones." We understood the determinants of underemployment and knew what to do about it. But now the previously rearguard actions of separate groups of neoclassicists and monetarists have been seen by some as a full-fledged challenge to basic Keynesian theory. And at the policy level, professional as well as public bewilderment grows through months of increasing inflation *and* unemployment.

Whence emanated the "underemployment equilibrium" fondly exposited to a captive generation of students and all others who would listen? We all did see the truth of Keynes's denial of the second of the two "classical . . . postulates," that "the utility of the wage . . . is equal to the marginal disutility of . . . employment." But why? Was it rigid wages because of irrational or institutional constraints? Was it rigid wages due to perfectly rational choice in view of imperfect information, search costs, and inelasticity of expectations with regard to future wage offers? Or after all, is wage rigidity, whatever the reason, an explanation of "equilibrium" in the general level of prices and unnecessary to an explanation of underemployment?

It is this last that we can properly attribute to Keynes, not merely the "Keynesians," to evoke Axel Leijonhufvud's distinction—and I mean by Keynes, *The General Theory*, not necessarily the *Treatise* to which Leijonhufvud would also have us refer. To Keynes, wages were not perfectly flexible downward; we need not be detained as to the reason, whether Keynes's own explanation or the current, sophisticated views in terms of information and search costs. And it is also true that Keynes viewed the monetary authority as deficient in its efforts and methods to keep the quantity of money sufficient to minimize long-term rates of interest. But it is important to see, both in terms of theory and policy, that wage frictions and monetary restrictions, while both sufficient conditions, were not necessary for Keynesian unemployment. This relates rather to an aggregate of individual preferences which do not bring about current consumption of total product and the lack of an *intertemporal* price structure which can insure the production now of capital goods for the future in an amount equal to the gap between consumption and the total production that would be effected by full employment.

It has been customary to compartmentalize the deficiencies in effective demand. On the one hand, consumption, for a variety of reasons relating to individual preferences, would be both bounded and fairly inelastic over plausible ranges of rates of intertemporal substitution. Investment, or the demand for current production of capital goods, is constrained by two blades of a scissors: production possibilities of functions which underlie expected rates of return and the long-run rates of interest which may be viewed as a cost or rental price of capital or rate of capitalization of expected future returns. Looked at either way, the possible rate of investment in a free economy is also bounded, and this I would insist is Keynes and not merely "Keynesian," as Leijonhufvud argues.

---

* William R. Kenan Professor of Economics, Northwestern University, and research associate of the National Bureau of Economic Research. I am indebted for helpful comments to R. A. Gordon, Harry G. Johnson, and Robert M. Solow.

Implications of rational choice and some evidence (Eisner, 1963, 1971) substantiate the possibility of a positive liquidity trap. Past history, including a history of rate variability, risk, risk aversion and information and transaction costs, indicates that at any point of time the public may be ready at some positive rate of interest to turn all of its bonds or other income-earning assets into cash and indeed, contrary to Don Patinkin (p. 349), issue more promises to future payments—bonds—than are currently in existence in return for additional cash. The liquidity blade of the scissors, however, need not be set at a positive rate of return. It suffices for the theory of underemployment that the blade be nonnegative; and we can hardly suggest a willingness to lend or invest at negative rates of return as long as there is any nonwasting, noncostly asset such as money.

It is the other blade of the scissors that has been questioned, originally explicitly by Frank Knight, with antecedents going back at least to Eugen v. Böhm-Bawerk, later by "Keynesians" such as Robert Solow and James Tobin, by Dale Jorgenson implicitly in his self-named "neoclassical investment function," and most recently by Leijonhufvud. One can appeal to considerable if disputable econometric evidence that investment demand is relatively inelastic, over plausible ranges, to available rates of intertemporal substitution, where these should depend upon both nominal interest, or expected earnings rates, and expected rates of price change. One can resort to casual empiricism or *gedank*-experiments which might suggest that, at any available technology, *profitable* investment opportunities are finite, or recall that a capital addition must, to be profitable, not only add to gross product but must add more than its original cost. Or one may merely look to the total structure of Keynesian theory and recognize that, were there no problem of matching *attainable* rates of interest to *acceptable* rates of return, Keynesian underemployment would vanish in reasonably functioning markets. Saving in excess of the investment demand at full employment would simply enough bring about a fall in the rate of interest sufficient to raise investment demand, if not reduce saving, to the appropriate equilibrium.

Clearly, rigid or downwardly inflexible wages are a sufficient condition for persistent unemployment in the face of a decline in aggregate demand. But while wages may in fact not be perfectly flexible, Keynes's argument was that, even if they were, full employment would not be assured. Given unemployment, with a nominal quantity of money held constant or which does not decline in full proportion with wages and prices, real cash balances would rise, thus lowering the rate of interest and raising the real value of outstanding bonds. The lower rate of interest would increase investment demand, but because of the shape of the liquidity preference function and ultimately, if it ever came to that, the liquidity trap, and the limited interest elasticity of investment demand, this "Keynes effect" would prove insufficient. The higher real value of bonds could raise consumption by those who are net holders of bonds. But unless there were an outside debtor such as a government, for whose real obligations the public (out of money illusion) would have no concern, or which would have a different horizon or set of time preferences, the increased real value of bonds for net creditors would be offset by a corresponding increase in the real obligations of net debtors. As for cash itself, this would have to be or correspond to a net asset of the public, perhaps as "outside" or government money, and the government would have to follow a "monetary" policy which in effect, by holding the money supply constant or not letting it fall in proportion to prices, transfers real purchasing power to holders of cash.

The policy implications involved in all of this seemed clear for a long time to most economists. For one thing, keep interest rates as low as possible and have the central bank operate directly on the rates relevant to investment by buying *long*-term bonds. This would be a step in the right direction, but given the limits to how low the rate of interest could be pushed and given the limits to investment demand, further action in the way of fiscal policy to raise consumption might prove necessary, along with direct government participation to "socialize" investment.

An important implication of the theory and policy, sometimes implicit and sometimes explicit, was that "stabilization" meant maintenance of full employment. The appropriate policy was not to lop off booms but to fill in recessions. While Keynes was explicit on this last, a full consideration of the system, both as originally formulated and as we should see it more clearly now, reveals basic weaknesses and contradictions in conventional countercyclical policy.

With regard to monetary policy and the interest rate, countercyclical policy is inconsistent with full employment policy. For full employment, we want no monetary bar to maximum investment. This means that we want no shortage of liquidity, *current or expected*, to drive long-term interest rates above a minimum which might, with appropriate consumption and investment functions, be the natural rate. But every time the monetary authority curbs the money supply to fight an inflation or cut off a boom it raises interest rates. In so doing it makes all the less credible any policy of low long-term rates and vitiates its efforts to lower rates in the next recession.

While the self-cancelling effect of monetary shifts should have been implicit in original Keynesian formulations, difficulties in affecting consumption by countercyclical tax measures have become apparent with later formulations of the consumption function, particularly by Franco Modigliani and Richard Brumberg and by Milton Friedman (1957), and the ineffectiveness of the 1968 surcharges in combating inflation. If current consumption depends not merely on current income but on wealth and expected future income as well, a temporary increase in tax rates may have only a minor effect in curbing aggregate demand. And with regard to the investment function, we have come to see that the paths of the acceleration principle and, perhaps a fortiori, substitution effects involve fairly long, well-distributed lags and expectations of the profitability of investment which, however mercurial on occasion, are not always easily swayed by transitory considerations.

The common thread to difficulties that even a fully competitive system may have in returning to full employment, or in ever attaining it, stems from the often uncertain and often inconsistent ties between the present and the future. Thus interest rates may not fall far enough now because of expectations by many that they will be higher in the future. Workers will not accept lower wages now because they expect that if they wait or look longer they may find a better paying job in the future. Abandoning the fiction of tâtonnement and recontracting, sellers of goods and services may hold out in the expectation that if they wait their reservation prices will be met. (Of course, in a world of imperfect competition, a fall in demand may raise or lower prices or leave them the same, depending upon changes in elasticities of demand and the nature of marginal cost curves.) And there is no guarantee that expectations of future wants and future prices will determine consumption plans for the present and the future which will mesh with current and future investment.

Through all the recapitulations and revisions of theory, we should keep prominent the recognition that money is not omnipotent. Its supply and demand equations are undoubtedly more important than those for peanuts, but not in principle different. If the supply of peanuts is reduced, even to zero, there would be repercussions in other equations as the demand for substitutes is felt. Similarly, the supply of money, by any particular definition, can be reduced with a demand for (and creation of) money substitutes then increased. Since, as Robert Clower and others have reminded us, money may usefully be viewed as a factor of production, reducing its supply may well reduce real output precisely in association with rising costs, a matter to which we shall return.

And then tied to our recognition of long-run consumption functions, related to far more than current income, and investment functions which are inelastic, unstable, yet hard to affect, is the critical fact of lack of perfect information and futures markets which would meet that lack. The only pervasive futures markets that exist are in money but even these are almost always in nominal terms. Except on cost-plus government contracts (the significance of which, as John Kenneth Galbraith has eloquently reminded us, should not be overlooked) producers can rarely guarantee their profits by sales of futures to match spot purchases of capital, labor, and materials. The lack of such futures markets at every stage may lead sellers, producers, and buyers to hold back, in risk aversion and uncertainty, leaving demand and output deficient in comparison with what they might be if all markets, for present and future goods and services, could be cleared currently.

This suggests, by way of policy, fiscal measures to change intertemporal price expectations. Instead of varying taxes on income, which have a wealth effect almost certain to be in the same direction for both current and future consumption, government should vary tax rates on goods and services. In some periods tax rates may become negative, that is, turn into subsidies, in order to encourage expenditures. In other periods, tax rates would be raised in order to discourage expenditures. Changes would be pointedly temporary to encourage intertemporal substitution. Thus when demand is deficient, tax rates on goods and services can be reduced temporarily with an explicit warning that they are likely to be raised in the future when demand may prove too high. The difference between a 10 percent subsidy and a 10 percent tax, for example, may well entail a sufficient shift in intertemporal price expectations to have a substantial effect on current demand.

And instead of permanent equipment tax credits, investment allowances, or accelerated tax depreciation, government might much better institute high but variable tax and subsidy combinations on investment expenditures generally, including nonprofit institutions and state and local governmental units as well. Thus, in periods when investment expenditures are to be encouraged, subsidies might run not to 7 percent but to 14 or 28 percent of any expenditures above, say, depreciation charges or an average of the last three years' investment expenditures. Where investment expenditures are to be discouraged, the subsidy can be converted to a tax. Again, knowledge that taxes and subsidies are temporary would generate a low, possibly negative, elasticity of effective price expectations and major intertemporal substitution of investment expenditures.

Tax policy may also be used to affect directly the demand for labor services. Where employment is slack, payroll taxes can be cut or suspended, or even converted into subsidies to encourage employers to hire workers. Where inflationary bidding up of wages has taken place, payroll taxes can be raised, perhaps particularly on *increases* in payrolls beyond what they were previously. And all of this focuses directly on the root cause of Keynesian departures from (hopefully not inflationary) full employment equilibria: a lack of an appropriate set of intertemporal prices or price expectations.

By further way of policy, certain old prescriptions for full employment still offer a sound foundation. As Evsey Domar long ago suggested, a governmental "guarantee" of a steady growth of income, in part presumably through a steady growth in "autonomous" government expenditures, tends to generate the investment and consumption demand which brings the economy to full employment. Along with this should go a fairly steady growth of the money supply, consistent with both Friedman (1968) and Keynes.

But beyond that, recognition of public concern with inflation, if nothing else, dictates the formulation of policies to improve the inflation-unemployment tradeoff. There are many obvious things that could be said about firm government action to promote competition. Too often ignored are the mass and maze of government institutions, actions, and policies which contribute to inflation. These include tariffs, import quotas, price supports, resale price maintenance, petroleum prorationing, regulatory authorities that keep rates up, purchasing and hiring policies that raise prices not only for what government buys, but for all buyers in direct or indirect competition with government.

To the objection that elimination of barriers to competition may have a once-over effect of lowering prices but no long-run influence on the rate of inflation, one should raise the "ratchet effect." Inflation may stem as much from nonfalling as from rising prices. In any functioning economy, demands and supplies are perennially changing. Some prices must hence be expected to rise while others fall. If tariffs, regulators, or monopolists "protect" us from price declines, the average movement of all prices can only be upward.

On the positive side, government can move to improve markets in general, and notoriously imperfect labor markets in particular, by utilization of modern information-processing techniques to match jobs to workers, not only locally but anywhere in the nation. Planning, encouragement, training and retraining, and subsidization should be used to bring to full employment both the transiently unemployed and the stubborn hard core. Indeed, beyond usually defined full employment, much can be done to expand the voluntary labor force by facilitating the freeing of slaves of domestic labor and seeing to it that there is optimal investment in the human capital of all of our population, including women, minorities, and the historically disadvantaged.

While we have suggested sobering considerations regarding the efficacy of both monetary and fiscal policy for combating cyclical fluctuations, there are a number of things that can be done, both to bring about greater stability and achieve "prosperity without inflation and without war," to repeat some words which might well be taken as more than rhetoric. For one thing, cut massive military expenditures, which have peculiar inflationary properties. In addition to adding to the income-expenditure stream without offering corresponding supplies of goods to private markets, the nature and aura of military purchases and the symbiotic relation of public buyers and private suppliers offer a strong suggestion of inflationary potential. But government taxes which relate directly to final products or factors clearly raise prices. One could stimulate demand *and* combat inflation by cutting excise taxes and payroll taxes and by subsidizing certain production, such as mass transit services, which may be particularly desirable in terms of positive externalities (or the ability to substitute for other production with negative externalities). Further, we could abandon the curious combination of high interest rates and business taxes, which in the long run must in at least considerable part be passed on to consumers, and special tax subsidies, such as equipment tax credits and accelerated depreciation, which compensate or more than compensate for some these charges which are imposed on all. And finally, while I have not introduced distributional considerations, I might venture a considered judgment that the package of policies to which I have pointed would on balance cater well to egalitarian tastes.

If economists can free themselves from old *political* ideas and advocate boldly what makes economic sense, the Keynesian revolution, appropriately refined and revised, may yet carry the day. For "soon or late, it is ideas, not vested interests, which are dangerous for good or evil."

Keynesian Models of Recession and Depression

By JAMES TOBIN*

Keynes's *General Theory* attempted to prove the existence of equilibrium with involuntary unemployment, and this pretension touched off a long theoretical controversy. A. C. Pigou, in particular, argued effectively that there could not be a long-run equilibrium with excess supply of labor. The predominant verdict of history is that, as a matter of pure theory, Keynes failed to prove his case.

Very likely Keynes chose the wrong battleground. Equilibrium analysis and comparative statics were the tools to which he naturally turned to express his ideas, but they were probably not the best tools for his purpose. For one thing, he explicitly confined the *General Theory* to a time period in which are given "the existing skill and quantity of available labor, quality and quantity of available equipment, the existing technique" and other factors. As he said (p. 245), "in this place and context, we are not considering or taking into account the effects and consequences of changes in them." But his model produces a solution in which, in general, the stock of capital, and other stocks, are not constant. Changes in these stocks will in turn alter investment, saving, and other behavior. For this reason alone, the solution of Keynes's model cannot be stationary, even in its own endogenous variables; and on this ground alone, it fails to qualify as an equilibrium. The evolution of Keynesian equilibrium as stocks change is receiving a great deal of attention these days and I shall not dwell on this point here. (See, however, A. S. Blinder and R. M. Solow and J. Tobin and W. Buiter.)

The second important point, the one on which Pigou insisted, is that excess supply of labor must cause money wages to decline. Even if this did not succeed in eliminating unemployment, one might not call a situation in which money wages and prices are persistently falling an equilibrium. But of course Pigou went further in contesting Keynes's claim that a "trap" might exist from which the economy could not be rescued, however low the wage and price level.

Keynes tried to make a double argument about wage reduction and employment. One was that wage rates were very slow to decline in the face of excess supply. The other was that, even if they declined faster, employment would not—in depression circumstances—increase. As to the second point, he was well aware of the dynamic argument that *declining* money wage rates are unfavorable to aggregate demand.[1] But perhaps he did not insist upon it strongly enough, for the subsequent theoretical argument focused on the statics of alternative stable wage levels.

The real issue is not the existence of a

---

* Sterling Professor of Economics, Yale University. The research described in this paper was undertaken by grants from the National Science Foundation and the Ford Foundation.

[1] ". . . it would be much better that wages should be rigidly fixed and deemed incapable of material changes, than that depression should be accompanied by a gradual downward tendency of money-wages, a further moderate wage reduction being expected to signalise each increase of, say, 1 percent in the amount of unemployment. For example, the effect of an expectation that wages are going to sag by, say, 2 percent in the coming year will be roughly equivalent to the effect of a rise of 2 percent in the amount of interest payable for the same period. The same observations apply *mutatis mutandis* to the case of a boom." (See Keynes, p. 265.)

long-run static *equilibrium* with unemployment, but the possibility of protracted unemployment which the natural adjustments of a market economy remedy very slowly if at all. So what if, within the recherché rules of the contest, Keynes failed to establish an "underemployment equilibrium"? The phenomena he described are better regarded as disequilibrium dynamics. Keynes's comparative statics were an awkward analytical language unequal to the shrewd observations and intuitions he was trying to embody. If the purity of neoclassical equilibrium is preserved, this verdict is no real blow to Keynes or solace for Pigou. The Great Depression is the Great Depression, the notorious "Treasury View" is still ridiculous, whether mass unemployment is a feature of an equilibrium or of a prolonged disequilibrium.

The issue is by no means dead. Today "full employment" has become the "natural rate," and "equilibrium" often allows for any steady rate of deflation or inflation, not just zero. But the proposition which Keynes was questioning is once again strongly argued in the profession and in public debate. Once again it is alleged that the private market economy can and will, without aid from government policy, steer itself to full employment equilibrium. This is the basis for advocacy of fixed rules of monetary growth and fiscal policy, as against active discretionary policy responding to information fed back from the private economy. At this very moment it is the basis for a policy of letting the recession run its course, in confidence that in a relatively short run—two or three years—equilibrium will be restored at full employment with reduced or even zero inflation.

I. Keynesian and Marshallian Price Dynamics

Milton Friedman (p. 18) has pointed out that Keynes was a "Marshallian in method" and translated the supply-demand framework of Alfred Marshall from individual markets to the whole economy. "Where he deviated from Marshall, and it was a momentous deviation, was in reversing the roles assigned to price and quantity. He assumed that, at least for changes in aggregate demand, quantity was the variable that adjusted rapidly, while price was the variable that adjusted slowly, at least in a downward direction." Friedman is correct that this was a momentous deviation, and one way to appreciate the point is to look explicitly at the dynamic stability implications of Walrasian vs. Marshallian assumptions about quantity adjustment.

Marshallian adjustment in a particular market is that quantity adjusts to the difference between demand price and supply price for existing quantity. Walrasian adjustment is that quantity adjusts to the difference between demand and supply at existing price.

Let us now apply these two adjustment assumptions to a simple macroeconomic model. Let Y be aggregate real output, and Y^* its value at full employment, i.e., at the "natural rate" level of unemployment. Let E be aggregate real effective demand, which can differ in short-run disequilibrium both from Y and from Y^*. Given the nominal stock of outside money M and other exogenous or policy-set variables, effective demand E is a function $E(p, x, Y)$ of three variables: p the price level, x its expected rate of change, and Y the level of output and real income.

In finer detail, E is the sum of consumption C, private investment I, and government purchases G:

$$(1) \quad E = C\left(Y, Y^*, -T, -R, x\frac{M}{p}, W\right) + I(Y, Y^*, -K, -R) + G$$

Here the C and I functions have positive derivatives in all their arguments. T represents taxes, a function of Y and Y^*. W is private wealth, equal to

$$\frac{M}{p} + qK,$$

where the coefficient q is the ratio of market valuation of capital equity to replacement cost. An increase in the real interest rate R relative to the marginal efficiency of capital makes q fall, and makes investment fall. The marginal efficiency of capital depends positively on Y and Y^*, negatively on K. The real interest rate R depends inversely on both M/p and x, and rises with Y and W.

The *price level effect* E_p on demand is negative, for the following familiar combination of reasons. First is the Keynes effect. A given nominal quantity of money will be a larger real quantity at a lower price level. Consequently the interest rate may be lower, and investment demand higher. The Keynes effect is expected to be weaker the larger the real supply of money relative to output Y, and to vanish altogether in the "liquidity trap." This will tend to make E_p smaller in absolute value at low levels of Yp/M.

Second is the Pigou effect, the wealth effect on consumption. The lower the price level, the higher the real value of those components of net private wealth fixed in nominal value. The relevant components are outside money (and some part of any nonmonetary public debt in existence). Consumption demand is expected, *ceteris paribus*, to respond positively to increases of wealth.

The short-run Pigou effect is very likely weaker than the long-run effect and may not even have the same negative sign. And it is the short-run effect which is relevant for Keynesian theory and for the dynamics of this paper. The difference arises as follows: among the stocks fixed in the short run are private debts in the unit of account. These are a heavier burden to debtors the lower the price level, and there are good reasons why transfer of real income and wealth to creditors spells a net deficit of aggregate demand. Debtors are debtors because they have high propensities to spend. Many of them are liquidity-constrained, and as their debt/equity ratios increase their credit lines dwindle or, in case of bankruptcies, disappear. Although these are "only" distributional effects, they may be more important than the real value of outside money and debt.

The long-run comparative-static Pigou effect, in contrast, assumes that each alternative price level has prevailed for a sufficiently long time so that inside debts are scaled to that price level—although strangely enough exogenous outside money is not. In this counterhistorical "as if" mental experiment, debtors are no more burdened at one price level than at another.

As for *the price change effect* E_x, there are several effects. A decrease in the expected inflation rate raises the real rate of interest. This increase discourages investment, and it also deters consumption both directly and by lowering the market value of equity capital, one component of wealth. On the other hand, expected capital gains on money holdings xM/p are favorable to consumption. This is a "flow Pigou effect," to be distinguished from the stock effect. The question here involves the size of the marginal propensity to spend from expected real capital gains. Econometric evidence has been that this marginal propensity is small, although capital gains eventually affect consumption via the wealth effect. I have assumed that the other effects of expected inflation dominate the flow Pigou effect.

The *marginal propensity to spend* E_y is taken to lie between 0 and 1 on usual Keynesian grounds. As is well-known, a high response of investment demand to contemporaneous income could easily make E_y exceed one. But Keynes typically regarded investment as determined more by long-run sales and profit expectations than by current business activity. The likelihood that, in prolonged departures from full employment, investment will come to be governed more by contemporaneous than by full employment sales and profits is a source of possible instability and of prolonged disequilibrium to which I shall return later in the paper.

In equilibrium, the following three conditions hold:

$$E(p, x, Y) - Y = 0 \tag{2.1}$$

$$Y - Y^* = 0 \tag{2.2}$$

$$x = \dot{p}/p = 0. \tag{2.3}$$

(I shall also denote $\dot{p}/p$ as π.)

I shall call the first dynamic version of this model the *WKP* model (Walras-Keynes-Phillips). All the adjustment functions which follow will conform to the notation $A_y z$, where y is the variable adjusting, z the variable on which the adjustment depends, and A_y a positive constant. The *WKP* model is as follows:

The WKP Model

$$\dot{Y} = A_y(E - Y) \tag{2.1.1}$$

$$\pi = A_p(Y - Y^*) + x \tag{2.2.1}$$

$$\dot{x} = A_x(\pi - x) \tag{2.3.1}$$

Equation (2.1.1) says that production Y moves in response to discrepancies of E and Y. This implements the Keynesian view that in the very short run money wages and prices are set and output responds to variations of demand.

How can E and Y diverge even for an instant? Many words have been spilled, both by Keynes himself and by others, on this question, usually posed in terms of the possibility of inequality of Saving and Investment. In our present context, let D be the demand which must always equal Y to preserve the national income identities. Let D be a function of $\dot{Y}$ as well as of x, p, and Y. Then $D(\dot{Y}, x, p, Y) = Y$, $E(x, p, Y) = D(0, x, p, Y)$. Equation (2.1.1) follows from a negative value of $\partial D/\partial \dot{Y}$, which means that demand is lower, at given Y, when Y is increasing. Lags in consumption spending lead to this sign and so does *unintended* inventory decumulation. The investment accelerator works in the other direction, but for the reason already given it is not a Keynesian idea.

Equation (2.2.1) is a natural-rate version of the Phillips curve. The short-run Phillips curve is the obvious Keynesian version of price dynamics. Throughout this paper I am condensing product and labor markets into one sector and assuming with Keynes that prices are determined by marginal variable costs, i.e., by labor costs. Excess labor supply and $Y - Y^*$, the "Okun gap," are linked,—when one is zero so is the other. So it is the gap which causes wage rates to fall. But to "fall" does not mean to decline absolutely; it means to decline relative to x, the accustomed and expected rate of inflation of both labor costs and prices. This is the more modern wrinkle. By here assuming (2.2.1) I do not mean necessarily to associate myself—much less Keynes!—with the natural-rate hypothesis in all its power and glory.

The third equation (2.3.1) is the well-known model of adaptive expectations. There is nothing particularly Keynesian about this equation, and the same formulation will carry over to the non-Keynesian dynamic model. Keynes himself would scorn it and stress instead the stochastic and historical sources of expectations. But like so many of his observations, these do not lend themselves to simple formal analysis.

As two extremes of interest I shall wish to consider:

$$x = \pi \tag{2.3.2}$$

(extrapolation of current rates of price *change*)

$$x = 0 \tag{2.3.3}$$

(extrapolation of current price *level*)

The alternative dynamic version may be called the M model (Marshall). The equations are:

The M Model

$$\pi = B_p(E - Y) + x \tag{2.1.2}$$

$$\dot{Y} = B_Y(Y^* - Y) \tag{2.2.2}$$

$$\dot{x} = A_x(\pi - x) \quad \text{(or 2.3.1 or 2.3.3)} \tag{2.3.2}$$

As compared with the WKP model, the adjustment roles of the first two equations are interchanged. The first equation now says that the immediate impact of excess demand for goods and services is to raise prices, or more strictly to raise them faster than they had been expected to rise. (It is not entirely accurate to regard (2.1.2) as non-Keynesian. When there is an inflationary gap ($E>Y^*$, $Y=Y^*$), this looks very much like the Keynesian model of inflation. But in Keynes's inflation theory, Y^* is considered an absolute short-run constraint on production, as in wartime. In normal conditions, Keynes would, I think, regard Y^* as a medium-run labor market equilibrium with normal margins of excess capacity and of frictional unemployment, a level of output which could be at least temporarily exceeded.)[2] In any event, equation (2.1.2) is one way to inject into the model the view that prices respond quite flexibly to changes in excess demand for goods, whether or not the economy is close to full employment.

The non-Keynesian partner of this price adjustment equation is (2.2.2), where the gap between potential and actual output inspires adjustments of production and employment. This is because they are associated with gaps of the same sign between the demand price for labor (the value of its marginal product) and its supply price.[3] The idea is that when Y^* exceeds Y the real wage is less than marginal productivity. Competitive employers therefore add to their work forces and their production. In Keynesian theory, on the other hand, production increases only when demand at existing prices expands.

II. Local Stability of the Two Models

Let us now consider the local stability of the WKP and M models, around their equilibrium values $Y=Y^*$, $p=p^*$, $x=0$. For this purpose it is convenient to substitute in the third equation the value of $\pi - x$ drawn from the second or first equation. Thus the third equations in the WKP and M models become respectively:

$$\dot{x} = A_x A_p(Y - Y^*) \tag{3.1}$$

$$\dot{x} = A_x B_p(E - Y) \tag{3.2}$$

For the WKP model, the linearized equations are:

$$\begin{bmatrix} \dot{Y} \\ \dot{p} \\ \dot{x} \end{bmatrix} = \begin{bmatrix} A_Y(E_y - 1) & A_Y E_p & A_Y E_x \\ A_p p^* & 0 & p^* \\ A_x A_p & 0 & 0 \end{bmatrix} \cdot \begin{bmatrix} Y - Y^* \\ p - p^* \\ x \end{bmatrix} \tag{3.3}$$

The critical necessary condition for stability is:

$$p^* E_p + A_x E_x < 0 \tag{3.4}$$

The first term of (3.4) is negative and the second term positive. As would be expected, a strong negative price-level effect on aggregate demand, a weak price-expectation effect, and a slow response of price expectations to experience are conducive to stability. In one extreme case (2.3.3), where $x=\dot{x}=0$, the system is of course stable. In the other extreme case (2.3.2), where $x=\pi$, the first term of (3.4) drops out and the system is necessarily unstable.

---

[2] In the *General Theory*, Keynes discusses frictional and involuntary unemployment on p. 6 and, in defining involuntary unemployment on p. 15, says, "Clearly we do not mean by 'involuntary' unemployment the mere existence of an unexhausted capacity to work."

[3] This is true even if the labor supply curve is downward sloping, provided it is closer to vertical than the schedule of marginal productivity of labor.

The M model is quite different. It is separable into output and price equations. Equation (2.2.2) is a stable differential equation in the single variable Y. The stability of the price system depends on (3.4), in the same way as the stability of the WKP model. The formal system is:

$$(3.5)\quad \begin{bmatrix} \dot{Y} \\ \dot{p} \\ \dot{x} \end{bmatrix} = \begin{bmatrix} -B_Y & 0 & 0 \\ B_p(E_Y-1)p^* & B_pp^*E_p & B_pp^*E_x+p^* \\ A_xB_p(E_y-1) & A_xB_pE_p & A_xB_pE_x \end{bmatrix} \cdot \begin{bmatrix} Y-Y^* \\ p-p^* \\ x \end{bmatrix}$$

As Friedman surmised, Keynes's choice of adjustment mechanisms is a crucial element of his theory. In particular, the Walras-Keynes-Phillips adjustment model allows the distinct possibility that lapses from full employment will not be automatically remedied by market forces. Keynes could also be interpreted to hold the view that price-level effects E_p are weak relative to speculative effects E_x. I shall discuss this interpretation further in the next section.

III. Irreversible Recessions and Deep Depressions

Let us take a more global look at the equilibrium condition $E=Y$ (2.1). In Figure 1 are shown in (p, x) space several loci along which the condition is met. The slope of such a locus, $-E_x/E_p$, is positive. Each locus is for a given value of Y; a reduction in Y shifts the locus to the left. In the Figure, the right-most locus is for full employment output Y^*. The weakening or vanishing of the "Keynes effect" at low values of Y and p tends to reduce E_p in absolute value. This is reflected in the curvature of the loci.

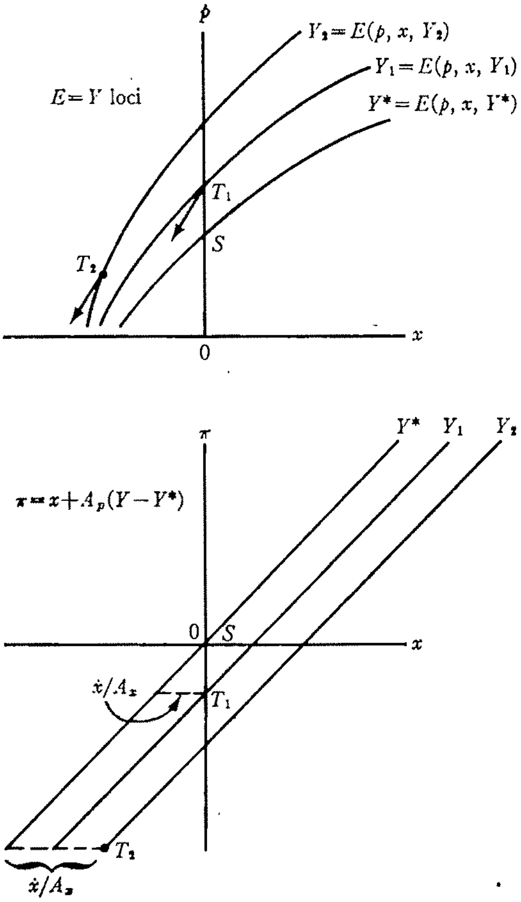

FIGURE 1

Consider an initial position T_1 at levels of E and Y short of Y^*. Prices begin to decline because Y_1 is less than Y^*. To a degree that depends on the speed of adaptation, expectations of price change become negative. The arrow indicates the direction of movement. As drawn, the movement is stabilizing, taking the economy to higher E and Y, toward Y^* and the equilibrium S.

The lower panel of Figure 1 concerns the direction of the arrow, the relationship of π and x. The horizontal axis matches in origin and scale that of the upper panel. The lines are parallel 45 degree lines, for Y^*, Y_1, and Y_2, the same output levels as in the upper diagram. The points S, T_1, T_2 correspond to the similarly labeled points above. At S, $\pi=0$. At T_1, π is negative. So is $\dot{x}$, by an amount proportional to the difference between π and x, shown horizontally as $\dot{x}/A_x$.

Consider instead an initial position T_2 in the two panels. At T_2 both the slope of the $E=Y$ locus and that of the arrow are steeper. The reason that the arrow is steeper can be seen in the lower panel: $\dot{x}/A_x$ has doubled, but π has more than doubled. The net outcome could go either way. The possibility illustrated is that at T_2 the locus $E=Y$ is so steep that the movement is destabilizing. The system might be stable for small deviations from its equilibrium but unstable for large shocks.[4] The failure of automatic market processes to restore full employment would be reinforced if large and prolonged recession caused investors to gear their estimates of the marginal efficiency of capital more to current than to equilibrium demand and profitability.

Under these adverse circumstances, and in the absence of countercyclical policy, the economy could slip into a deep depression.

In nonlinear nonmonetary business cycle models like those of M. Kalecki, R. Goodwin, and Sir John Hicks, a long depression phase occurs with the economy at a floor. At this floor the capital stock is excessive and gross investment is zero; production is solely to meet minimal private and social consumption requirements, which are independent of income and wealth. The depression phase lasts a long time, while depreciation slowly whittles the capital stock down to the amount needed for floor level production.

It is not part of this paper to provide a model of such a floor. The relevant question is whether deflation will by itself lift the economy from the floor. Will deflation so augment private wealth that consumption rises above its floor level? Clearly this will not happen unless condition (3.4) is met at the depression income level.

But at the floor, E_x is higher than in the normal regime. An increase in the deflation rate $-x$ lowers the value of the capital stock. The physical capital stock declines slowly. But its value—its *real* value—can decline rapidly; when no gross investment is taking place, the existing stock will be valued well below replacement cost. At the liquidity trap, the real interest rate is the irreducible nominal rate $\bar{r}$ plus the expected rate of deflation $-x$. The value of a unit of capital is $(\rho-\delta/(r-x))$ where $\rho-\delta$ is the marginal productivity of capital net of depreciation. Although the attrition of the stock slowly raises ρ, deflation rapidly raises $\bar{r}-x$.

IV. Concluding Remarks

God may have made the world so that full employment equilibrium exists and is stable. Perhaps the divine design guarantees that capitalist market economies will never be trapped in depressions with involuntary unemployment and will never need to depart from fixed no-feedback rules of fiscal and monetary policy. But Keynes had good empirical and theoretical reason to suspect otherwise. He did not establish an underemployment equilibrium. But he did not really need to. Even with stable monetary and fiscal policy, combined with price and wage flexibility, the adjustment mechanisms of the economy may be too weak to eliminate persistent unemployment.

---

[4] Robert Solow has pointed out to me that the possibility illustrated by T_2 is only suggestive of a global instability. The global properties of the system require further investigation.

PERSONAL SAVINGS IN THE POSTWAR WORLD: IMPLICATIONS FOR THE THEORY OF HOUSEHOLD BEHAVIOR

Towards a Theory of Saving Behavior

By F. THOMAS JUSTER AND LESTER D. TAYLOR*

The behavior of personal saving in the *U.S.* economy has long held a fascination for economists. The earliest consumption functions, based on cross-sectional data from household budget surveys, indicated that richer households save more relative to income than poorer ones, leading to the Keynesian speculation that secularly rising income would result in higher saving rates. The monumental study of *U.S.* capital formation of Simon Kuznets indicated that this attractive theory did not square with the facts, since there was no evidence that saving as a fraction of income increased as income rose secularly.

This apparent contradiction between cross-sectional and long-term time-series evidence attracted a great deal of attention in the late 1940's and early 1950's and led to the formulation of three new theories of the consumption function, the relative income hypothesis of J. S. Duesenberry, the life-cycle hypothesis of F. Modigliani and R. Brumberg, and the permanent-income hypothesis of Milton Friedman.[1] Although these theories, especially the last two, have inspired a huge literature, its main strands really have had little to say about cyclical movements in personal saving, as opposed to secular movements.[2]

While focusing on the secular behavior of saving was understandable in the 1950's and early 1960's when the personal saving rate moved within fairly narrow limits, the saving rate in recent years has been considerably more volatile. This cyclical volatility has been a concern of both Juster and Taylor in recent years, and the present undertaking represents a merging of efforts. The focus of Taylor's work has been on the role of income composition in determining the behavior of aggregate saving, while Juster has concentrated on the role of uncertainty.[3] The present paper attempts to combine both of these insights into a more refined model of personal saving.

I. Income Composition and Adjustment Effects

Excluding the effects of uncertainty, which will be discussed below, the general framework for our analysis is the "zero-depreciation" theory of saving elaborated by H. S. Houthakker and Taylor. According to this theory, personal saving (S) is assumed to be a linear function of the existing stock of financial assets (A) and income (Y):

$$S(t) = \alpha + \beta A(t) + \gamma Y(t). \tag{1}$$

The stock of financial assets is assumed to be nondepreciating, with the result that the relationship between the stock A and its flow S is given by

---

* University of Michigan and University of Arizona, respectively.

[1] A fourth theory, developed by James Tobin, involves an extension of the absolute-income hypothesis of Keynes that takes into account the household's level of wealth.

[2] For a detailed review of the permanent-income hypothesis and critical evaluation of the many and various attempts to test it, see T. Mayer.

[3] See Taylor (1971 and 1974). Also, see Juster (1973) and Juster and P. Wachtel (1972a and 1972b).

$$(2) \qquad \dot{A}(t) = S(t).$$

The basic notion underlying the model is that the consumer adjusts saving to bring the stock of financial assets into line with income. This model can be interpreted as embodying a Stone-Nerlove stock adjustment process to the stock of wealth, with the proviso that the depreciation rate on the stock is zero. An important consequence of this assumption is that saving is zero in long-run, steady-state equilibrium. Accordingly, the concept of a marginal propensity to save must be with reference to some limited interval of time. More particularly, γ in equation (1) refers to the instantaneous marginal propensity to save defined by the condition that the underlying stock of financial assets is constant. However, γ should not be confused with the one-quarter marginal propensity to save which will be the focus in the empirical work.

Following Taylor (1971), one of the objectives of our inquiry requires disaggregation of disposable income into the following components: labor income (L), property income (PR), transfers (TR), personal contributions to social insurance (SI), and personal tax and nontax payments (T). With this decomposition of disposable income, equation (1) becomes

$$(3) \quad S(t) = \alpha + \beta A(t) + \gamma_1 L(t) + \gamma_2 PR(t) + \gamma_3 TR(t) + \gamma_4 SI(t) + \gamma_5 T(t).$$

Since savings are the epitome of a durable good, β should be negative: the stock of wealth should have the same (qualitative) effect on saving that the stock of automobiles, say, has on the sale of new cars. The coefficients γ_1, γ_2, and γ_3 should, of course, be positive and on theoretical grounds γ_2 should be greater than γ_1 because property income is more uncertain than labor income. The marginal propensity to save out of transfer payments has traditionally been thought to be low, but all empirical work to date with this model has found γ_3 to be in the neighborhood of .8. Finally, γ_4 and γ_5 are naturally expected to be negative, and since contributions to social insurance leave the contributors with a claim to future income—rather than just a tax receipt—the size of γ_4 will depend upon the extent to which social insurance substitutes for regular saving. At an extreme, γ_4 could be in the neighborhood of -2, since employees' contributions are matched dollar-for-dollar by employers.

As formulated in (3), the model contains a quantity, the stock of financial assets, that can at best be measured with difficulty, hence it is desirable that it be eliminated. Once this is done, and also after the model is translated into one involving discrete intervals of time, the estimating form of the model, with an error term (u) added, becomes:[4]

$$(4) \quad S_t = B_1 S_{t-1} + B_2 \Delta L_t + B_3 \Delta PR_t + B_4 \Delta TR_t + B_5 \Delta SI_t + B_6 \Delta T_t + u_t.$$

The coefficients $B_1, \ldots, B_6$ are functions of the structural parameters $\beta, \gamma_1, \ldots, \gamma_4$ (α is indeterminate), and estimates of the latter can be readily obtained from estimates of the former.

II. The Role of Uncertainty

Economists have long paid lip service to the role of uncertainty in affecting economic behavior, but attempts to quantify the impact of uncertainty have been few and far between. Empirically, uncertainty regarding income usually takes the form of supposing that people make judgments about the future on the basis of past behavior of the quantities in question. However, for reasons that need not be discussed at length, the customary procedures seem to us to be seriously deficient, and we feel that there may be some real payoff in devising direct measures of uncertainty that are both relevant and operational.

---

[4] The details of this elimination and translation are set out in Houthakker and Taylor, pp. 13–17. For the formulae involved, see p. 17.

Following Juster and P. Wachtel (1972a) and Juster (1973), our approach takes into account two types of uncertainty that are expected to influence saving behavior. The first type is the conventional kind of uncertainty regarding income. If consumers become concerned that money income may fall, they can be expected to react by trying to build up cash balances via increased saving. If money income actually falls, the fixed-cost elements of consumption expenditures can be expected to result in lower saving. Empirical representation of these effects can be accomplished by using the unemployment rate to measure money income that is high or low relative to the recent past, and to use the change in unemployment rate as a measure of changes in the degree to which consumers attach uncertainty to the receipt of future money income. Thus, unemployment is expected to have a negative impact on current saving, since it represents a negative transitory income effect, while the change in unemployment is expected to have a positive impact on saving.

The second, less conventional, and perhaps more important, dimension of uncertainty has to do with the effects of price inflation on saving. A recent paper by Wachtel (1974) suggests a useful classification for the effects of price inflation on saving: a money-illusion effect, an intertemporal substitution effect, and an uncertainty effect.

The first two of these effects are traditional subjects of analysis, but the third is a relatively recent and more speculative insight and is based on an idea long espoused by George Katona that rising pessimism regarding the future results in higher rates of saving. As elaborated by Juster (1973), the key ingredient is the downward inflexibility of money wage rates. In a world where money wage rates cannot fall, a zero rate of price inflation implies that changes in real wage rates cannot be negative. Consequently, uncertainty about the change in real income is limited to uncertainty about how large an increase in money wages will be forthcoming.

However, when prices are rising, real income can fall if money wages fail to rise as rapidly. Moreover, the higher the rate of price inflation, the greater the possible downward movement in real income. Viewed more generally, the distribution of the expected change in real wages is determined jointly by the distribution of the expected change in money wages, the distribution of the expected change in prices, and the relationship between these two quantities. Only in the extreme case of automatic and complete indexing will the existence of price inflation (of uncertain magnitude) not lead to greater uncertainty about real wages than in a world where price inflation is absent.

While price inflation per se is sufficient to generate uncertainty about the change in real income, the measure that best represents the kind of uncertainty that impacts on saving behavior might well be the maximum price rise considered "plausible" by consumers. That is, saving may be more influenced by judgments about plausible upper limits of future price increases than by estimates of the most probable change in prices. Although we do not have a direct measure of these upper limits, it does not seem unreasonable to suppose that the variation among households in the expected change in prices provides some useful indirect information.[5]

III. Empirical Results

The empirical analysis employs quarterly data, mostly taken from the National Income Accounts (*NIA*), and covers the period beginning with the second quarter of 1953 and ending with the fourth quarter of 1973. The *NIA* data are aggregates, seasonably adjusted at annual rates, expressed in billions of current dollars. The price expectations data come from surveys conducted periodically by the Survey Research Center at the University of Michigan.[6] The conventional *NIA* definition of personal saving is the saving concept that is analyzed.

Of the numerous equations estimated, five have been selected for presentation and discussion and are tabulated in Table 1. The first equation is included for purposes of comparison with Taylor's earlier efforts with the model based on equation (3) above. The relevant equation from Taylor (1971) is as follows: (t-ratios are in parentheses):

$$\begin{aligned}(4)\quad S_t = \underset{(43.79)}{.955S_{t-1}} &+ \underset{(4.21)}{.449\Delta L_t} + \underset{(0.86)}{.277\Delta PR_t} \\ &+ \underset{(2.86)}{.893\Delta TR_t} - \underset{(-3.30)}{2.16\Delta SI_t} \\ &- \underset{(-4.87)}{.901\Delta T_t} + \underset{(2.03)}{3.65\Delta BAA_t} \\ &R^2 = .899 \quad S_e = 2.01 \quad df = 61.\end{aligned}$$

The period of fit for this equation was 1953–I through 1969–IV.

The most notable difference between the first equation in Table 1 and equation (4) involves the coefficients for labor income and property income. The coefficient on ΔPR is now greater than the coefficient on ΔL, which is what we expect a priori, and now has a t-ratio approaching 2. This emergence of property income as a somewhat energetic predictor would seem to result from recent sharp increases in farm proprietors' income. Apart from this, the coefficient on the change in payroll taxes increases, but nevertheless remains less than -1. Note, too, that the impact of a change in transfers on saving is still substantial.

The remaining four equations in Table 1 incorporate the various uncertainty measures just discussed. Equations were estimated with ΔU as a predictor as well as U, but it was invariably weak statistically and therefore has been excluded

---

[5] For example, if all households expect prices to rise at the rate of zero percent per year, this may not be very different in terms of the impact on saving than if, *ceteris paribus*, all households expect prices to rise at a rate of 10 percent per year. But if there is a great deal of dispersion in "best guesses" about the extent of future price rises, this dispersion may be taken as a reasonable proxy for concerns about plausible upper limits. In any event, this variation across households represents the only empirical measure of uncertainty that we have, except, of course, for the mean expected price change across all households.

[6] The questions are relatively straightforward: "Do you expect prices to rise or fall or what?" and, starting with the first quarter of 1966, "How much do you expect prices to rise—1 or 2 percent, 3 or 4 percent, 5 percent, between 5 and 10 percent or more?" Estimates of the mean and variance of expected price change among the population sampled can be constructed either by assignment of quantitative magnitudes to basically qualitative responses for part of the period (i.e., until 1966) and assignment of midpoints for that part of the period for which quantitative data are available or by a less arbitrary, but perhaps also less satisfactory, procedure of throwing away all quantitative detail and focusing simply on responses in the up, down, no-change categories. The latter, concentrating only on direction of change, can be converted into estimates of means and variances, provided that one is willing to assume a specific distribution for expected price within the population sampled.

Both types of estimates have been used in the empirical analysis. As it turns out, the best results are obtained with the mean constructed by the second procedure and the variance constructed according to the first. The question of which procedure to employ is far from closed, however, and both we and others are attempting to improve upon our methods for constructing estimates of expected price change from the available survey information.

TABLE 1—REGRESSION RESULTS OF U.S. PERSONAL SAVING
Quarterly 1953-II—1973-IV
(t-ratios in parentheses)

Independent Variable	Equation

Note: The variables are defined as follows: S = personal saving; L = labor income (equals sum of wage and salary disbursements and other labor income); PR = property income (equals proprietors' income, rental income of persons, dividends, and personal interest income); TR = transfer payments; SI = personal contributions to social insurance; T = personal tax and nontax payments; BAA = yield on Baa bonds; $CPI^* = (\Delta CPI_t + \Delta CPI_{t-1})/2$; PE = mean expected price change;[a] VPE = variance in mean expected price change within population sampled[a]; U = civilian unemployment rate.

[a] The methods of calculating PE and VPE are described in an appendix, obtainable on request from the authors.

from consideration. Equations 3 and 5 in the table have the yield on Baa bonds and the uncertainty measures interacted with the level of disposable income. The purpose of this was to allow for the possibility that the effects of uncertainty on saving vary systematically with the level of income. The results, however, do not suggest that this is the case. Finally, equations 2 and 3 differ from 4 and 5 in that 2 and 3 include the most recent six-month change in the consumer price index (*CPI*) as a predictor in place of the mean expected price change.

Addition of the uncertainty measures to the model leads to the following results and conclusions:

(1) Except for the unemployment rate, the signs of the uncertainty measures are all as expected a priori.[7] In particular, the results strongly support the conclusion that uncertainty regarding the future course of real and money income leads to an increase in saving.

(2) Of the uncertainty measures considered, the strongest statistically is the variance term. As suggested by the discussion in Section II, we interpret the strong performance of this variable as representing the impact on saving of uncertainty regarding plausible upper limits to the amount of price inflation.[8]

(3) The coefficient on payroll taxes is reduced considerably in absolute value and is now of the same magnitude as the coefficient on personal tax and nontax payments. Taking equation 4 as the point of reference, the only other coefficients to undergo much change (vis-à-vis equation 1) are those on S_{t-1} and labor income. The former is reduced to .83, which implies a speedier dynamic adjustment, while the latter is increased by about one-third. It is of particular interest that the inclusion of the uncertainty measures does not alter the statistical significance of the income terms. And it is especially to be noted that the coefficient on the change in transfer payments remains large.

(4) Finally, it is to be noticed that the coefficient for the yield on Baa bonds is negative, while the coefficient for its first difference is positive. Since the factors operating on the real rate of interest should be expected to change slowly through time, the first difference in the nominal rate of interest should, in view of Irving Fisher, be dominated by price expectations. This being the case, the positive coefficient on ΔBAA is very much in keeping with the views expressed in Section II. However, the negative coefficient for *BAA*, in an expectations framework, is harder to interpret.

[7] The discussion in Section II viewed the unemployment rate as a proxy for (negative) transitory income, hence it was postulated that its sign should be negative. However, the fact that this is not the case suggests that the unemployment rate augments the price expectations variables as a direct measure of uncertainty.

[8] There are, of course, other hypotheses that can be advanced to account for the importance of *VPE*. In particular, we are especially interested in exploring the possibility that *VPE* represents an aggregation effect arising from variation in the impact of price expectations on saving across income groups. Nevertheless, the fact remains that, for whatever reason, *VPE* is an important predictor empirically.

Saving Behavior in Western Germany and the United States

By BURKHARD STRUMPEL*

Sharp cross-national differences in the saving behavior of private households are reasonably well documented but not well understood. The cross-country variance in the rate of saving has been explained only to a small extent by a country's income status, change, or trend. There are doubts if "one true world saving function in which saving is a function of current income" really exists (D. W. Johnson and J. S. Y. Chiu, p. 333).

Economic theory has repeatedly been criticized for the neglect of cultural and institutional constraints that restrict the validity of its laws. The problem of ethnocentricity has been discussed extensively in the fields of economic development and comparative economic systems, but much less so in other areas. The easy reaction to this criticism is to define time/space coordinates in order to limit the application of the theories in question. It is more constructive, however, to reformulate the theory in a fashion sufficiently general to incorporate the "deviant" cases. Starting out from the large and unexplained differences in the rates of household saving between Western industrial countries, this paper presents a model of household saving emphasizing its cultural and institutional determinants. It thus deals explicitly with some of the factors that shape a nation's saving behavior in reaction to given income conditions and that have not been treated by the well-known theories of the consumption function.

These theories have directed most effort towards alternative formulations of the explanatory variable income, its distribution across individuals in a society, its sources, and its change over time. Little attention has been given to the refinement of the dependent variables. Spending or saving, consumption or asset formation are mostly treated as aggregates only. They are not being differentiated according to their uses or their purposes as intended by the decision maker. According to Kevin Lancaster, utility is linked not only to a good but to the characteristics of a good as they are related to a variety of household goals or ends. Similarly, saving must be seen as instrumental for a variety of goals. Different people and nations, even those operating within similar income constraints, can be shown to differ widely with respect to the intensity of these goals, as well as the instrumental role of saving in reaching these goals. Why should the motivation to save for the purpose of acquiring a home respond to an income increase in the same manner as the inclination to accumulate reserves for emergencies or rainy days?

Adapting the expectancy-value approach, I see the motivation to save as dependent on:

(1) the strength of the goals that are to be served through saving (e.g., sense of security in case of emergencies; subsistence at old age; acquiring real estate or durables);

(2) the instrumentality of saving: To

---

* Program Director, Institute for Social Research, University of Michigan, and Visiting Professor of Economics, University of Frankfurt, Germany, for 1974–75.

what extent is saving perceived as indeed approaching or resulting in that goal?

(3) the strength of the motivation to spend; since saving and spending are subject to a common budget constraint, a strong motivation to spend will tend to depress saving, and vice versa.

This model will be used below to explain differences in rates of saving between Western Germany and the United States. The available evidence on goals and instrumentalities of saving, while suggestive, does not yet permit a quantitative test of the model as applied to a large number of countries or a long period of time. In this sense, the model is programmatic rather than definitive.

Table 1 exhibits some saving statistics in important Western countries and Japan for selected years between 1954 and 1973. As is well-known, there are considerable

[a] Includes private households, personal trusts, and private nonprofit organizations.

[b] Aggregate disposable income was calculated from U.N. National Accounts statistics by subtracting the following from "Current Receipts of Households": all direct taxes including income tax, compulsory fees, fines, and penalties, social security contributions, and current transfers to either nationals or to the rest of the world.

Sources: Various issues of the following sources were used: Federal Reserve Bulletin; Bundesbank Reports; German Statistical Office National Account Series; Financial saving figures for other *OECD* Financial Statistics; U.N. Yearbook of National Accounts for 1973, German Statistical Office, National Account Series; Statistical Abstract of the U.S.; National Income and Expenditure: 1963–73 (by the Central Statistical Office of Great Britain); Japan Economic Yearbook.

statistical problems connected with cross-national comparisons of saving. Total saving (col. 4) is measured as a residual, namely as the difference between disposable income and total disbursements by private households, and is thus subject to inaccuracies and errors in measuring either of the two components. Total saving differs from the much more reliable financial saving statistics (cols. 1 to 3) in that it comprises undistributed profits or investments in own unincorporated business. Net investment in consumer durables and housing does not enter into either of these figures. While the other saving statistics in Table 1 represent the balance of saving over dissaving, Social Security contributions are gross figures, i.e., not adjusted for benefit payments and thus cannot simply be added to either col. 1, 3, or 4.

Table 1 leads to the following conclusions:

(1) Both total saving and net financial saving have been consistently much higher in Germany than in the United States. This is so in spite of considerably more "forced saving" through the German Social Security system resulting in considerably more income continuity extending beyond the working years.

(2) There is great similarity in gross financial saving between Western countries (excepting Japan). The important differences in net financial saving enter through the item increase in consumer debt which has been extremely high in the United States.

(3) Social Security contributions differ drastically, separating Germany and France on the upper end from the Anglo-Saxon countries on the lower one.

(4) Rates of saving in the United States show more stability over time, continuing a long history (R. W. Goldsmith). European and Japanese rates, while more volatile, have increased somewhat during the 1950's and 1960's.

In the following, the higher saving performance of Germany compared to the United States is viewed largely as resulting from:

(A) a greater felt need for financial reserves providing protection for contingencies and rainy days, brought about by charactistically pessimistic expectations for the future;

(B) a perceptible trend toward satiation with consumer goods making it easier for a saving motive of given strength to be translated into behavior;

(C) a policy of subsidizing mass saving, thus strengthening the instrumentality of saving for medium and long-term accumulation; and

(D) the ingrained practice of saving in advance of purchasing real estate and consumer durables rather than incurring installment debt, thus making saving highly instrumental for acquiring consumer investment goods.

(A) The link between cyclical changes in attitudes of mass publics (perceptions and expectations about own economic situation and that of the economy) and the volume of consumer durables purchases had first been demonstrated for the United States by G. Katona and later replicated for Canada and Germany (H. T. Shapiro and G. E. Angevine; Strumpel, K. Novy, and M. S. Schwartz). Optimism tends to induce consumers to spend more because they may be more willing to borrow against future income flows or to reduce their level of or addition to precautionary savings relative to income, tending to perceive past accumulations of reserves as adequate or redundant (W. E. Dunkelberg). A persistent posture of economic pessimism in Germany in the face of prosperity, sharply contrasting with the mood of confidence characteristic, until recently, for American households, was reported by Katona, Strumpel, and E. Zahn, who conducted a cross-national comparison of household attitudes and economic behavior on the basis of national surveys in 1968. Close to half (43 percent) of all American heads of household anticipated being better off four years from now, but only a third of the Britons, a quarter of the French, Germans, and Dutch. Whereas every third American both felt better off than four years ago and anticipated being better off four years hence, only every fourth Briton, every fifth Frenchman, every sixth Dutchman, and every eighth German felt similarly embedded in a continuum of progress. The Germans by far most frequently among Western nations denied that they were living in an extraordinarily favorable era of rising real incomes. Responding to unexpected income stagnation, Americans have only recently abandoned their traditional optimism and are now approaching German levels of consumer sentiment.

(B) Insecurity about the economic future breeds an apprehensive posture toward consumption and spending. Higher living standards are a byproduct of progress on which Germans tend to look with reserve, almost with suspicion. The maintenance and preservation of past gains are foremost in people's minds rather than any longing for better living. In 1957, 48 percent of German adults stated flatly that they would be satisfied if their economic situation would remain as it was for the next five to ten years. This proportion rose to 60 percent in 1961 and to 70 percent in 1963. When asked whether they considered the present average standard of living in Germany to be too high, too low, or just right, the proportion of those who disapproved of prevailing levels of consumption as being too high increased from 52 percent in 1958 to 62 percent in 1963.

Thus it is not surprising to find consumption aspirations of Germans lagging behind accomplishments. A symptom of the lag is an uninterrupted, steep increase in the proportion of households which are close to feeling "saturated." Asked whether respondents intended to make large outlays during the coming year, the negative answers increased from 16 percent in 1956 to 20 percent in 1959, 31 percent in 1962, and 46 percent in 1967. While comparative survey data for the United States are lacking, social observers emphasize the terse race between aspirations and accomplishment.

According to R. G. Merton, "In the American dream there is no final stopping point. . . . At each income level . . . Americans want just about twenty-five percent more (but of course this "just a bit more" continues to operate once it is obtained)."

(C) Since the currency reform of 1948, Germany has developed by far the most comprehensive system for promoting saving by both private households and enterprises. Within certain limits per household, tax deductions or outright subsidies were granted for time deposits, contractual saving through building and loan associations (Bausparkassen), acquisition of certain stocks and bonds, and live insurance premiums. There are also government incentives for allocating part of workers' wages or salaries to asset formation. Together with the normal interest payments, these premiums (some of them discontinued) added up to an effective annual interest rate of 10 to 15 percent for the amounts in question and thus by far exceeded market rates. The variety of promotion programs led to a high degree of habitualization and contractualization of saving behavior and thus tended to relieve the motivation to save from the continuous competition with instant consumption.

Moreover, the high effective rate of interest accruing on the accounts amounts to large quasi-automatic increments in liquid assets. A given original saving effort has resulted in more asset formation than in the United States or other countries lacking an extensive system for promoting saving.

(D) There are large cross-cultural differences in the purposes of saving. In Germany, a large proportion of liquid assets is intended for purchases of consumer durables. While 59 percent of the German savers interviewed in 1967 mentioned such purchases, only 7 percent of Americans in 1966 referred to the same items (Katona, Strumpel, and Zahn). In the United States in the late 1960's, close to one-half of all families had some installment debt, and close to 40 percent of all families bought something on the installment plan each year in the 1960's. The best figure available for Germany is that in the late 1960's 11 percent of all families were making monthly installment payments. This proportion did not increase at all in the 1960's and, according to some surveys, may even have declined somewhat.

In the United States, purchasing a home requires only a small down payment. Buying a home in Germany is contingent on a larger proportion of cash, much of it generated by long-term advance saving in building and loan associations.

The difference between saving in advance of a purchase and saving afterwards through repaying debt does not necessarily result in a difference in overall saving rates. If in the United States incurrence of new installment debt were balanced every year by repayment of such debt, and if in Germany the amounts saved in advance were balanced by withdrawals from liquid funds to make cash purchases, the overall saving rates of the two countries would not be affected by the different practices. The fact is, however, that in the last ten years in Germany families have accumulated liquid funds beyond the amounts they have used while in the United States outstanding installment debt has risen year after year far beyond the amounts of repayments made. Thus in a growing economy, the mode of financing consumer durables does influence the rate of saving. On the other hand, a decrease in the growth of mass incomes as expected by many would tend to reduce the differential.

The substantial differences in both goals and uses of saving are not just of a short-lived, cyclical nature. The peculiar manner in which Americans on the one hand and Germans on the other have interpreted their respective economic experiences and have used their savings and their credit has persisted at least through the 1950's and 1960's when rapid economic growth was accompanied by moderate inflation. How could a period characterized by slow growth or stagnation combined with high rates of inflation affect the motivation to save? On the one hand, disappointment or bad times might invoke the need to prepare for a dim and insecure future. Goals for saving would become stronger. On the other hand, rapid inflation would drastically reduce the actual and perceived instrumentality of financial reserves: accumulation-oriented financial saving presupposes trust in the stability of institutions and a certain predictability (not necessarily stability) of the value of money. The data exhibited in Table 2 suggest that during the highly inflationary year 1973 many Italians and Frenchmen for the time being have written off saving as an appropriate vehicle for transferring purchasing power from the present to the future. The respective saving figures for that year are not yet available. Germans, in the face of a more moderate increase in inflation, maintain their highly saving-minded posture and—as the

TABLE 2—ATTITUDES TOWARDS SAVING IN A PERIOD OF INFLATION

recent record shows—manage to translate it into behavior. Also Americans, consistent with the drastic deterioration in economic sentiment, have stepped up saving recently. As in the past twenty-five years, the security-deficit created by inflation superseded the decline in instrumentality, i.e., the fear of erosion of the value of savings (see the preceding paper by F. Thomas Juster and Lester D. Taylor).

In the quarter century of affluence following World War II, Western industrial nations went through a historically unique period of rapidly rising mass incomes. During this time span, monetary reserves ceased to be a prerogative of the rich. The real asset value of the average household, both financial and tangible, has increased substantially. This is true primarily for the United States, constant rates of financial saving notwithstanding. The advent of financial discretion or latitude made it possible for the many to extend their sights to the future, to prepare for expected and unexpected needs through reserve formation rather than to live from hand-to-mouth and from day-to-day. To provide for the future became a powerful aspiration of the masses albeit of lesser priority than minimum material subsistence.

The actual trends in these countries then appear to be in accordance with at least two basic tenets of the theories of the consumption function. The absolute income hypothesis tends to view saving as a function of ability to afford it; it thus manages to capture the hierarchy of priorities as suggested by the recent saving history. Yet it fails to consider saving and its dynamics as dependent on concrete motives whose strength may not vary mechanistically with income. The permanent income and life-cycle hypotheses, while negating any motivational priority of minimal present consumption over future needs, are explicit about the goal of saving. In centering on the desire for continuity of consumption levels, they describe one powerful motive of income allocation in industrial societies. Yet the individual or collective goal of equalizing consumption over time continues to compete with immediate consumption and other saving motives and remains a lofty vision for many. For instance, poverty even in affluent societies is still heavily concentrated among the old, in some countries more, in others less. And the latter are by no means the richer ones, as would have to be predicted on the basis of the absolute income hypothesis.

The failure of the theories of the consumption function to satisfactorily explain cross-national differences in the rate of saving has two reasons. First, with respect to the dependent variable, the theories neglect the multiplicity of saving goals. Saving is a conceptual and statistical artifact; its components differ with respect to their behavioral and motivational sources and merit separate theoretical attention. Second, with respect to the explanatory variables, the theories deal exclusively with income and its changes. This paper suggests that institutional and cultural characteristics of a society largely shape the uses and functions of saving and thereby its motivational makeup.

Postwar U.S. Consumption, Consumer Expenditures, and Saving

By Michael R. Darby*

If interest in research topics ebbs and flows, there can be no doubt that macroeconomic consumption theory is again on a rising tide of fashion. This revival is the inevitable result of the greatly extended base of high quality data and of the central role of the consumption function in the debate between the dynamic and Keynesian approaches to macroeconomic theory.

The consumption theories developed in the 1950's by Milton Friedman and by Franco Modigliani and Richard Brumberg departed from that of Keynes in two significant ways: (1) the substitution of wealth for current income as the crucial determining variable, and (2) the substitution of consumption of service flows for consumer expenditures as the appropriate dependent variable. While this represented a substantial improvement over the Keynesian consumption function in the ability to explain the broad movements in consumption, it moved away from the key macroeconomic concept of consumer expenditures. Models must be developed which are appropriate to this latter concept.

Any successful explanation of consumer expenditures requires a clear distinction between consumption per se and consumer expenditures. This distinction is not "a theoretical nicety, inappropriate to empirical work."[1] Its neglect has led to some very large biases and bitter controversy over empirical magnitudes. I believe that the distinction is more than just empirically important. It is basic to a theoretical understanding of the transmission of monetary and other macroeconomic shocks.

I. The Relationship Between Consumer Expenditures and Consumption

Consumer expenditures, c_t^x, are quantitatively equal to consumption of service flows, c_t^f, plus the change in the stock of durable goods, Δd_t, less the implicit interest yield on durable goods, rd_{t-1}:[2]

$$c_t^x = c_t^f + \Delta d_t - rd_{t-1}. \qquad (1)$$

So there are three components to be explained by a theory of consumer expenditures: pure consumption, durables adjustment, and durables yield.

As is well-known, over long periods each of these components can be approximated as proportional to wealth or permanent income. In the short run, however, this approximation is unacceptable for the latter two components.

---

* Associate Professor, University of California, Los Angeles, and Harry Scherman Research Fellow, National Bureau of Economic Research, New York. Helpful suggestions were received from Armen Alchian, Phillip Cagan, and Arthur Gandolfi.

[1] M. J. Farrell (p. 679) complained of neglect of this distinction in 1959. It is present in the recent review article by Robert Ferber and the book by Thomas Mayer.

[2] All of these variables are measured in real terms. The real durable goods stock, d_t, is measured at the end of period t (beginning of period t+1). Equation (1) follows from the fact that $c_t^f = c_t^n + (r+\delta)d_{t-1}$ where c_t^n is the flow of purchases of nondurable goods and services, r the real interest rate appropriate to durable goods, and δ is the depreciation rate. Substitution in equation (1) yields $c_t^x = c_t^n + \delta d_{t-1} + \Delta d_{t-1}$ as required.

Pure consumption of service flows is properly assumed to be a fraction k of permanent income, y_{Pt}.[3]

$$c_t^f = ky_{Pt}. \tag{2}$$

Substituting equation (2) in equation (1) yields

$$c_t^x = ky_{Pt} + \Delta d_t - rd_{t-1}. \tag{3}$$

The stock of durable goods is the sum of past changes in the stock; so the explanation of short-run fluctuations in consumer expenditures concentrates on those changes.

II. The Estimation of Permanent Income

Before presenting an explicit model of durables stock adjustment, it is appropriate to comment briefly on implications of this approach for the construction of permanent income estimates. I (1974) have published a study of these implications elsewhere.

The permanent income hypothesis asserts that transitory income will alter pure consumption only in so far as it alters wealth. This implies that transitory income will be correlated with fluctuations in consumer assets including the stock of consumers' durable goods.[4] Neglect of this correlation between changes in the stock of durables and transitory income has led to specification error. The error arises in regressions which explain consumer expenditures—not pure consumption—by permanent income alone with transitory income omitted.

The standard analysis of bias due to omitted variables is inapplicable because permanent income is simultaneously estimated by an auxiliary equation

$$y_{Pt} = \beta y_t + (1 - \beta)(1 + g)y_{Pt-1}, \tag{4}$$

where β is the weight of current income, y_t, in the determination of permanent income and g is the trend rate of income growth. Selection of β so as to minimize the residual variance of the consumer expenditures regression, which is the standard procedure, leads to an upward bias of the β estimate.

Two interesting facts arose from my research on this statistical bias. (1) Substantial amounts of durable goods are officially classified as nondurable goods and services. These—such as clothing and shoes—biased upwards the weight of current income in permanent income even in studies such as Friedman's which replaced "durables" expenditures with their service flows. The estimated weight of current income in permanent income was reduced to about 0.1 on an annual basis. (2) The traditional permanent income estimator is derivable under the permanent income hypothesis from a perpetual inventory model of wealth. In that case the weight of current income in permanent income is the expected real yield on private wealth. The differences between permanent income and life-cycle models are thus primarily differences in techniques of estimating wealth.

III. A Consumer Expenditures Model

I will now complete the model of consumer expenditures by specifying a portfolio adjustment model of changes in the stock of consumer durables. By separating the pure consumption and portfolio adjustment decisions, many severe analytical hurdles are bypassed.

This research is still under way, but is sufficiently advanced that a progress report may be of interest. I am currently testing a generalized stock adjustment model of changes in the durables stock.

---

[3] There are several ways to derive this proportionality from maximizing behavior. Perhaps the simplest assumptions are a constant real yield r_p and infinitely-lived individuals with utility function homothetic in present and all future values of consumption.

[4] Empirical evidence for this proposition is presented in Darby 1972.

Changes in the durables stock are determined as the sum of four components: the normal change, a fraction of the difference in desired and adjusted actual stock of durables, a fraction of the difference between actual and permanent income (transitory income y_{Tt}), and a fraction of the difference between actual and desired real money balances.

$$(5)\quad \Delta d_t = (\Delta d_t)^e + \lambda_1(d_t^* - (\Delta d_t)^e - d_{t-1}) + \lambda_2 y_{Tt} + \lambda_3(m_t - m_t^*).$$

The first component of normal or planned change refers to the growth in the durable stock that would be associated with normal saving and growth in wealth. This amount would occur in the absence of any surprises and shocks.

The second component is a standard stock adjustment formulation adjusted for the existence of normal growth. This permits the long-run demand factors summarized by d_t^* to affect the rate of change of the stock.

The precise interpretation of the third component depends upon the view of permanent income and transitory income which is adopted. On the view taken in my restatement of the permanent income theory (1974), transitory income is unanticipated and therefore interpreted as a windfall change in wealth. Since it is received in nonhuman form, however, there will be a temporary change in all nonhuman consumer assets over and above that implied by the change in wealth alone. On the alternative view that transitory income is anticipated, it represents no change in wealth, but will be offset by future and past receipts of transitory income. So transitory income is saved in various asset forms. The first interpretation now seems to me the preferable one, and that approach is taken here.[5]

The final component—the excess demand for money—explicitly accepts the substitution explanation of the real balance effect. This specification is not restrictive empirically, however, since any wealth effect will increase the estimated coefficient of the real money supply without otherwise affecting the estimates.

In order to empirically estimate this equation, the normal change in the durables stock $(\Delta d_t)^e$, the stock demand for durables d_t^*, and the demand for money m_t^* must be specified. The stock demand for durables is assumed to be explained by a linear demand function in permanent income, relative price of durables P_{Dt}/P_{NDt}, and the long-term interest rate i_t:

$$(6)\quad d_t^* = \alpha_0 + \alpha_1 y_{Pt} + \alpha_2 \frac{P_{Dt}}{P_{NDt}} + \alpha_3 i_t.$$

The normal change in the durables stock is approximated as a constant times permanent income:[6]

$$(7)\quad (\Delta d_t)^e = \eta y_{Pt}.$$

Finally, the demand for money is taken as a function of permanent income, transitory income, and the long-term interest rate:

$$(8)\quad m_t^* = \gamma_0 + \gamma_1 y_{Pt} + \gamma_2 y_{Tt} + \gamma_3 i_t.$$

Combining equations (3) and (5) through (8) yields the complete model of consumer expenditures:

---

[5] This interpretation implies that transitory holdings of durable goods will be eliminated over time even in the absence of offsetting transitory income receipts. The alternative view was taken in Darby (1972). The view that transitory income increases or decreases wealth dollar for dollar is subject to criticism within the context of a neoclassical growth model. Many would object to the implied endogenicity of labor due to investments in human capital.

[6] Note that $\Delta d_t^* = \alpha_1 \Delta y_{Pt} + \alpha_2 \Delta(P_{Dt}/P_{Nt}) + \alpha_3 \Delta i_t$. If there is no expected trend in the two-price terms, $(\Delta d_t^*)^e = \alpha_1(\Delta y_{Pt-1})$, the expected growth in durables demand can be so approximated. Current permanent income is substituted for lagged permanent income in order to avoid problems of multicolinearity.

$$(9)\quad c_t^{x} = \beta_o + \beta_1 y_{Pt} + \beta_2 y_{Tt} + \beta_3 m_t + \beta_4 d_{t-1} + \beta_5 \frac{P_{Dt}}{P_{NDt}} + \beta_6 i_t + u_t.$$

On the derivation presented above, definite signs can be assigned only to β_3 (positive) and to β_4 and β_5 (negative), though there is a presumption that the negative impact of permanent and transitory income in increasing the real demand for money will not fully offset the otherwise positive impact.

An advantage of estimating equation (9) is that the form—though not the interpretation of coefficients—is robust with respect to several different ways of modeling the durable stock adjustment equation. Also the fact that the official definition of durable goods excludes substantial amounts of behaviorally durable goods is finessed to the extent that the stock of these quasi-durable goods moves similarly to the stock of the officially designated durable goods.

IV. Estimation of the Consumer Expenditure Function

The consumer expenditure function (9) may shed light on several outstanding empirical questions: (1) Does the estimate of 0.1 as the weight of current income in determining permanent income which was estimated on the basis of consumption flows hold up for consumer expenditures? (2) What is the proper definition of current income for use in explaining consumer behavior? (3) Which definition of the money supply seems most appropriate for the consumer expenditure function?

The first question has considerable personal interest, since it deals with the general applicability and consistency of the approach contained in my 1974 restatement. That question must necessarily be dealt with in the simultaneous estimation of equations (4) and (9).

The second question has been frequently raised of late. It is illogical that consumers should pay much attention to disposable personal income regardless of variations in saving on their behalf on the part of firms. Many researchers have found that the addition of this saving (undistributed corporate profits) to disposable personal income substantially improves their ability to explain consumer behavior. From the point of view of completeness, a more thoroughgoing definition of private sector income would be net national product less taxes net of transfers. This series should be adjusted for the yield on the stock of consumers' durable goods. From the point of view of a rational consumer, the inflationary tax on real base money should also be deducted in deriving the amount which can be allocated between consumption and increasing wealth.[7]

The third question refers to the possibility of using consumer expenditure data to provide information on the debate in monetary theory about the empirical definition of money. Similarly, estimation of permanent income on the basis of the demand-for-money equation may provide some further information on the weight of current income in the determination of permanent income.

These three issues must finally be considered simultaneously. Unfortunately the empirical investigation is still quite incomplete. Suggestive estimates are available, however, for a single combination of real income and real money stock definitions. Real private sector income adjusted for a 10 percent yield on the stock of consumer's durable goods and the narrow (M_1) money supply are the concepts used. The real stock of consumers' durable goods is extended from Darby 1972. The relative price of consumers' durable goods is based on the implicit price deflators indicated. The interest rate i_t is the market yield on long-term *U.S.* government bonds. All variables except the last two are measured in billions of 1958 dollars.

---

[7] Arguably the rate of inflation times at least part of the real government debt should also be deducted.

For annual data from 1947 through 1973, the estimated consumer expenditure function is:[8]

$$
\begin{aligned}
(10)\quad c_t^x = & -\underset{(57.90)}{143.6} + \underset{(.065)}{1.07}y_{Pt} + \underset{(.060)}{0.41}y_{Tt} \\
& + \underset{(.135)}{0.66}m_t - \underset{(.069)}{0.36}d_{t-1} \\
& + \underset{(36.3)}{27.3}\,\frac{P_{Dt}}{P_{NDt}} + \underset{(1.35)}{1.44}i_t \\
& \text{S.E.E.} = 1.996 \quad R^2(\text{adj.}) = .9996 \\
& D - W = 2.37
\end{aligned}
$$

The maximum likelihood value of β is 0.15 (to the nearest 0.01) with a greater than 90 percent probability confidence interval (0, 0.23).[9] The corresponding quarterly regression is:

$$
\begin{aligned}
(11)\quad c_t^x = & -\underset{(8.80)}{27.2} + \underset{(.032)}{0.87}y_{Pt} + \underset{(.036)}{0.45}y_{Tt} \\
& + \underset{(.025)}{0.19}m_t - \underset{(.009)}{0.034}d_{t-1} \\
& + \underset{(5.59)}{2.87}\,\frac{P_{Dt}}{P_{NDt}} + \underset{(0.22)}{0.38}i_t \\
& \text{S.E.E.} = 0.744 \quad R^2(\text{adj.}) = .9992 \\
& D - W = 1.07
\end{aligned}
$$

The maximum likelihood value of β is 0.005 (to the nearest 0.0025) with a greater than 90 percent probability confidence interval (0.0, 0.06). In comparing these two regressions, note that the flow variables c_t^x, y_t, y_{Pt}, and y_{Tt} are measured for the quarterly regression at seasonally adjusted *quarterly rates* in view of the stock-flow relationships.

A few comments on these results are in order. First the explanatory power: the ratio of the standard error of estimate to the mean is 0.59 percent for the annual data and 0.86 percent for the quarterly data. The two regressions correspond closely when the coefficients are adjusted for the different time units. The two stock variables—real money and the durable goods stock—enter statistically significantly and with the expected signs. The estimated values of the weight of current income in permanent income bracket the value of 0.10 per annum estimated in the previous work, though the differences are not statistically significant.[10] The coefficient of the relative price of durable goods P_{Dt}/P_{NDt} is statistically insignificant and of the wrong sign. This is not a surprising result since the prices of about half of all durable goods—in a behavioral sense—are included in the denominator because of misclassification. The significantly negative constant term is due to the positive constant in the demand for money.

The consumer expenditure function also provides a useful avenue to analyze saving behavior. The concept of saving which is directly applicable is private sector saving (private sector income less consumer expenditures). Again, this is the concept of prime interest to macroeconomists. It is trivial to show that private saving is determined by:

$$
\begin{aligned}
(12)\quad s_t = & -\beta_o + (1-\beta_1)y_{Pt} + (1-\beta_2)y_{Tt} \\
& - \beta_3 m_t - (\rho + \beta_4)d_{t-1} - \beta_5\frac{P_{Dt}}{P_{NDt}} \\
& - \beta_6 i_t - u_t,
\end{aligned}
$$

---

[8] Standard errors are given in parentheses below the coefficients.

[9] Computed on the basis of the asymptotic distribution of the *log* of the likelihood function. The likelihood function is rather flat between 0 and 0.2, after which it drops rapidly.

[10] In further work, it is found that this weight is closer to 0.1 if the years 1947 through 1953 are dropped from the regression. Whether this is due to peculiarities in the data—such as those due to price controls—or in the initial values selected for the permanent income or durables stock is unknown.

where the β_i's are as in equation (9) and $\hat{r}$ is the imputed yield on the durables stock.[11] Regression fits of equation (12) correspond with regressions (10) and (11). The model explains private saving very well, with a standard error of estimate only 5.0 percent of the mean for annual data and 7.5 percent for quarterly data.

The long-run stability of the ratio of private saving to private sector income does not hold in the short run because of fluctuations in the levels of transitory income, real money balances, and the real durables stock. There is no reason to expect stability of the ratio of personal saving to personal disposable income over any period.

V. Summing Up

If the research does not yet permit conclusions, it does suggest a point of view. The long-run pattern of consumer expenditures conforms to a trend-dominated measure of permanent or normal income. Short-run deviations of consumer expenditures reflect three main influences: (1) transitory income, (2) the real money supply, and (3) the real durables stock. The first measures the current rate of change in nonhuman assets relative to normal saving. Given permanent income and transitory income, real money balances enter as a measure of the excess money supply. Higher real money balances have a very clear and economically significant effect on directly increasing real consumer expenditures while lower real money balances directly decrease real consumer expenditures.[12] The level of the real durables stock has a definite negative impact on the rate of consumer expenditures due both to their implicit yield and to stock adjustment.

There is much work yet to be done to examine the impact of the alternative definitions of income and money on the estimated weight of current income in permanent income. Statistical problems of simultaneity, auto-regressive residuals, and suspect 1947–53 data also arise.

It seems to me that a strong case has been made, however, for formulating aggregate consumer expenditure functions instead of consumption functions. The general approach of equations (1) and (4) provides a broad framework for other researchers to develop improved models of the adjustment of the durables stock or even of pure consumption. This combined approach is less sensitive than attempts to convert the data into pure consumption with respect to what are little more than arbitrary decisions as to what is and what is not a durable good. And, of course, consumer expenditure functions have the advantage of explaining the variable of interest to macroeconomists.

[11] That is, 0.1 per annum for annual data and 0.025 per quarter for quarterly data.

[12] This provides strong support for the monetarist proposition that changes in the money supply shift the *IS*—as well as the *LM*—curve.

DISCUSSION

Thomas Mayer, University of California, Davis: Michael Darby's paper is a very competent piece of work. He uses standard econometric techniques in a sophisticated way, but still I am uneasy about his results. This is so primarily because I feel uneasy about the validity of our standard techniques, not because of the particular way he uses them.

One difficulty with standard techniques appears when one asks what is new about Darby's results: In what way do they differ from the standard view? His use of both permanent income and transitory income is fairly standard by now. Moreover, his finding that the coefficient of permanent income is about twice the coefficient of transitory income is consistent with the bulk of the empirical evidence. Specifically, it is consistent not only with a modified permanent income theory such as Darby presents, but also with a theory intermediate between the permanent income theory and the older theories, a theory which has households consuming both out of permanent and transitory income directly. Similarly, his inclusion of the money stock and the interest rate in the consumption function is also consistent with previous work. To be sure, the relative price variable is normally not used, but since it has the wrong sign, it really does not belong in Darby's function either. Finally, his *d* variable has been used by Hendrik S. Houthakker and Lester D. Taylor.

This raises the question whether the detour via the consumption of durable services is really needed. Darby could have written out the function he actually tested directly, based on a general theory of household behavior. It can be derived from a much broader range of theories than the permanent income theory. For example, in Darby's model the transitory income term enters as a part of the permanent income theory because some so-called nondurables are actually durables. But one could also say that households consume directly out of transitory income. Hence, one can accept Darby's equation without accepting his permanent income theory. This, of course, is a common problem in econometric work. When reduced to testable propositions, quite different hypotheses come up with the same equation and therefore cannot be tested against each other. However, one result of Darby's paper is new. This is the very low value of beta, and hence the very long lag in the formation of permanent income. But as discussed below the evidence for this is not very strong.

A second problem with time series regression tests is that many quite arbitrary decisions inevitably have to be made and poor proxies have to be used. For example, Darby simplifies by treating the desired stock of durables as proportional to permanent income. But why should the income elasticity of durables be equal to unity? Second, Darby explains the inclusion of the money stock as representing an allowance for a portfolio adjustment process. But why confine a portfolio adjustment process to money; why not include savings and loan shares, etc.? Third, the inclusion of the money stock creates a problem of reverse causation since an increase in consumption, by raising interest rates, is likely to cause the Federal Reserve and the banks to raise the money stock. (Obviously, the transitory income variable and the interest rate also have a potential for "reverse causation.") Fourth, the interest rate variable is measured badly. As Milton Friedman has rightly insisted, the observed interest rate on securities is a very poor measure of the expected real rate of return which households can obtain from holding a wide variety of nonmoney assets. (Darby uses a bond rate as his measure of the interest rate. A composite deposit rate on bank time deposits, savings and loan shares, mutual savings bank deposits, and consumer loan rates would have been better since, until recently at least, households did not buy bonds to any significant extent.) Fifth, since quality improvements have probably been more important for durables than for nondurables, the relative price variable is probably measured quite badly, and it is therefore not surprising that it has the wrong sign. (But upon finding that it has the wrong sign, Darby should have eliminated this variable and rerun his regression without it.) Sixth, Darby forms his permanent income estimate by using a maximum likelihood procedure in which the computer is allowed to select the beta coefficients which maximize R^2. But this commonly used—and perhaps only available—technique is of questionable validity. Recently I tried to test the validity of goodness of fit tests by comparing the ranking of various hypotheses by goodness of fit during the sample period with their ranking when projected beyond the sample period. And the results were not encouraging, to put it mildly. Finally, while I like Darby's adjustment for corporate savings, I am not sure that it goes far enough; perhaps other capital gains should be included too. The fluctuations observed in the price-earnings ratio suggest that corporate savings is not a reliable guide to expected capital gains.

Hence, there exist a large number of points on which Darby's paper can be criticized. But this does not mean that he did his econometrics badly. Unlike many discussants, I do not want to give the impression that had I been the author I would have avoided such mistakes and have done the job much better. This is *not* the case. The problems I have outlined result primarily from the absence of good proxies, and from other problems which are inevitable in econometric work. But since these problems do exist, I believe that Darby's results, while interesting and suggestive, are far from conclusive. The way to obtain more conclusive results is to run many tests using different sets of data and different techniques. If such tests all essentially tell the same story, then and only then can one conclude that a strong case has been made. And I welcome Darby's study as one step along this path.

Turning briefly to the F. Thomas Juster-Lester D. Taylor paper, here too existing techniques have been used very competently. But again, our standard regression techniques reveal a weakness. Adding the uncertainty variable raises the explained variance only slightly, though significantly so. (The standard error of estimate falls substantially. But since this error is very low in any case (only 6 percent of the mean of the dependent variable) it probably is not a good measure of the performance of the equation beyond the sample period.) To be sure, since the fit is already good prior to the addition of the uncertainty variable, one could hardly expect more, but even so, I am left with *some* doubt. But the uncertainty variable is one which is highly appealing on a priori grounds, and Juster and Taylor's paper is therefore very useful in showing that a variable which a priori seems to belong in the consumption function actually does improve the fit of the consumption function.

MICROECONOMIC THEORY: CONFLICT AND CONTRACT

A Contractarian Paradigm for Applying Economic Theory

By JAMES M. BUCHANAN*

The object for economists' research is "the economy," which is, by definition, a *social organization*, an interaction among separate choosing entities. I return deliberately to this element in our primer, because I think that it has been too often overlooked. By direct implication, the ultimate object of our study is not itself a choosing, maximizing entity. "The economy" does not maximize, and we may substitute "the polity" here without change in my emphasis. No one could quarrel with these simplistic statements. The inference must be, however, that there exists no one person, no single chooser, who maximizes *for* the economy, *for* the polity. To impose a maximizing construction on the models that are designed to be helpful in policy is to insure sterility in results.

Where did economics, as a discipline, take the wrong turn? My own suggestion is that Lionel Robbins marks a turning point. His book defined "the economic problem" as the location of maxima and minima. Almost simultaneously with this, the Edward H. Chamberlin and Joan Robinson books marked a turning inward, so to speak, a shift toward the maximizing problem of a specific decision-making entity. The economics of the firm was born, to be followed by the Hicksian elaboration of the economics of consumer choice. Paul Samuelson put this all together in his *Foundations of Economic Analysis*. Importantly, he extended the maximizing construction to welfare economics, extolling the virtues of A. Bergson's social welfare function as the tool through which such extension was made possible. For a quarter of a century, we have witnessed many variations on this theme, with economists hither and yon maximizing objective functions subject to specific constraints.

I should not imply that the maximizing models have held monolithic dominance. The institutional economists, and their successors, have continued their sometimes inarticulate critique of economic theory. Frank Knight, and some of his students, continued to lay stress on the social-organization aspects of the discipline. Game theory, in its solution rather than its strategy search, offered partial redirection of emphasis. More importantly for my purposes, public choice theory emerged as the positive theory of politics, a theory that necessarily treats individual decision takers as participants in a complex interaction that generates political outcomes.

But let me return to mainstream efforts of economists in the years since World

---

War II. I have no quarrel with the elaborations and refinements of the maximizing models for individual and firm behavior, although I have argued that many of these contributions belong, appropriately, to home economics or to business administration rather than to political economy. My strictures are directed exclusively at the extension of this basic maximizing paradigm to social organization where it does not belong. This is the bridge which economists should never have crossed, and which has created major intellectual confusion. "That which emerges" from the trading or exchange process, conceived in its narrowest or its broadest terms, is not the solution to a maximizing problem, despite the presence of scarce resources and the conflict among ends. "That which emerges" is "that which emerges" and that is that.

Return to game theory for analogy. The solution to a game with defined rules is not a maximum, and an external observer of the game would not attempt to seek improvements by operating directly on solutions. He would, instead, look at the prospects for changing the rules, and observed solutions would be information inputs in his evaluation of the game. Solutions are not directly "chosen" by a welfare function that embodies the preferences of the players, and solutions are not themselves ordered in terms of such a function. In game theory, the attempt to force such a construction would appear (and be) absurd. Yet this seems to me to be precisely what economists try to do within their analogous domain. Game theorists would indeed be surprised if someone should find that solutions could, in fact, be ordered in any manner that was consistent with the values of individual players. And they would not be profoundly shocked, to say the least, if someone should prove that such an ordering could not be made. Yet is this not what most economists experienced when Kenneth Arrow published his famous impossibility theorem in 1951?

My own initial reaction to Arrow's work was, and remains, one of nonsurprise (see Buchanan 1954). Who would have expected any social process to yield a consistent ordering of results? Only economists who had made the critical methodological error of crossing the bridge from individual to social maximization without having recognized what they were doing would have experienced intellectual-ideological disappointment.

There is no need to limit discussion to Arrow's theorem, although I shall return to this. Economists crossed the bridge from individual to social maximization because they wanted to be able to say something about policy alternatives. They desperately needed some instrument which would allow them to play the social engineer even if they eschewed the explicit intrusion of their own values in the process.[1] With the social welfare function construction, they could then talk as if their policy statements were operationally meaningful, and this ability provided them with a certain inner satisfaction. They have remained unwilling to utilize the Pareto criterion as a mere classification scheme, which Ragnar Frisch had advised them to do, and they have not followed my own suggestion (1962) about shifting the application of the criterion back to the level of institutional choice, where prospects for mutuality of agreement are enhanced.

How would the abandonment of the social maximization paradigm have changed the research thrust of economic theory, especially its potential relevance for social policy? The Pareto criterion classifies all positions into two mutually exclusive sets. Once an initial position is explicitly identified to be "nonoptimal" or "inefficient," we know that there exists at least one means of moving from this position to a position that falls within the optimal or efficient set. The initial position must be dominated, for all persons, by at least one position in the efficient set.

---

[1] I am indebted to Charles Plott for suggesting this explanation of the Bergson-Samuelson approach, which is a more sympathetic explanation than the one which I have elsewhere suggested.

There is no issue here, but what should be the role for the economist who has completed these first steps in applying his expertise? He should neither revert to nihilism nor seek the escapism of social welfare functions. His productivity lies in his ability to search out and to invent social rearrangements which will embody Pareto-superior moves.[2] If an observed position is inefficient, there must be ways of securing agreement on change, agreement which signals mutuality of expected benefits. In the limiting case, compensation schemes can be worked out which will achieve Wicksellian unanimity. Yet how many economists do we observe working out such schemes? How many economists bother with proposed compensations (which must, of course, include structural-institutional rearrangements) to those who will be overtly harmed by the effects of a public or governmental policy shift?[3] Instead of this potentially constructive effort, we find our colleagues continuing to express opposition to tariffs, quotas, minimum wages, price controls, depletion allowances, monopolies, tax loopholes, etc., whether these be existing or proposed. And they continue to stand surprised when the political process, as it operates, pays little or no heed to their advice. As Knut Wicksell noted eighty years ago, economists act as if they are advising a benevolent despot, in which case their post-Robbins, post-Bergson stance would, of course, be entirely fitting.

There is a place for efficiency in my suggested scheme of things. In this sense, there is little wrong with economic theory per se. Efficiency, as an attribute, is necessarily present when there is a demonstrated absence of possible agreed-on changes. The trading process, broadly conceived, is the means through which the "potentially realizable surplus" is exploited. But there is no uniquely determinate outcome of the trading process, since exchanges must be made and contracts enforced at preequilibrium and, hence, disequilibrium prices. Under the standard assumptions, simple exchange insures that an efficient or optimal position is attained, but this is only one from among a set containing a subinfinity of possible positions. Economists should be satisfied with this result. Within theory itself, search for uniqueness seems to be misguided effort. When the standard assumptions are not descriptive, the simple exchange process will not generate efficient results, and more complex arrangements may be called for. But these arrangements may still be examined in a contractual framework. The specification of these complex contractual arrangements may challenge the skill of the practicing political economist. In facilitating these complex exchanges, which may require the inclusive membership of the whole group, collective-governmental institutions may be necessary. And even though unanimous agreement for change may be conceptually possible, the costs of reaching agreement may be acknowledged to be prohibitively high. This suggests, in turn, that rules or institutions for reaching collective or group decisions may be preselected at some constitutional stage of "trade." It becomes possible in this way to apply the basic contractarian paradigm to the discussion of possible agreement on rules, even if it is anticipated that conflict will emerge at some final stage of application.

---

[2] This is essentially the suggestion that I made in my paper in 1959.

[3] An exception is W. H. Hutt. In a much neglected small book published in 1943, he proposed that the postwar British economy be swept clear of all market restrictions through the device of compensating all persons and groups who would lose by the change.

Whether the contractarian paradigm is applied at the level of simple exchange, within the constraints of well-defined rules, or at the most basic constitutional level where institutions themselves are the objects upon which agreement must be reached, or at any intermediate level, the emergent results of the trading process are properly summarized as a set of optimal positions, each one of which represents a possible outcome, and no one of which dominates any other in the set. This statement is enough to suggest my prejudices toward game-theoretic explorations into mathematics as opposed to the intricacies of complex maximization. The continuing search for solution concepts—the J. von Neumann-O. Morgenstern solution set of imputations, the several cores along with other more sophisticated concepts—seems to me to reflect and in turn to foster an attitude in the theorist that is consistent with, and contributory to, the contractarian approach that I am here suggesting.

The modern efforts to prove that competitive equilibrium exists and lies in the core of an economy are within my own limits for methodological legitimacy. The complementary emphasis here should be placed on the multiplicity of possible equilibria, on the absence of uniqueness. The devices of the Walrasian auctioneer or Edgeworthian perfect recontracting have been required for the proofs here, but I urge those skilled in this particular mathematics to search for theorems that require less stringent assumptions, that incorporate trading at disequilibrium prices.

Now let me return, as promised, to the Arrow impossibility theorem. In his Nobel Prize lecture, Arrow (1974) offers a lucid summary of modern economic theory, and he concludes with a discussion of his impossibility theorem. Unfortunately, Arrow does not seem to have gone beyond his initial failure to appreciate the inconsistency between his norms for a social welfare function, or choosing process, and the precepts for a society of free men. In his lecture, Arrow makes it clear that the Bergsonian requirement of "collective rationality" is prior to the set of reasonable conditions that he lays down for his social ordering. Having long ago proved that these conditions cannot be met, Arrow continues to hold that "the philosophical and distributive implications of the paradox of social choice are still not clear." This statement is both surprising and personally disappointing, since it indicates that Arrow has paid no heed to the arguments which I have made, along with many others, against the whole notion of collective rationality.

The so-called paradox may be used as a single and simple illustration of the profound difference between the maximization paradigm and the contractarian one. There are three voters, A, B, and C, and three alternatives, 1, 2, and 3. The collective choice rule is simple majority voting. Through a series of pairwise comparisons, individual preference orderings may be such that 1 is majority-preferred to 2, and 2 is majority-preferred to 3, while 3 is majority-preferred to 1. This cyclical result is disturbing only to those who seek uniqueness in outcome, who seek to impose the maximization paradigm on a social interaction process where it does not belong. By contrast, to those who accept the contractarian paradigm, who seek only to explain and to understand the behavior of persons who interact, one with another, there is nothing at all disturbing in the paradox. On the assumptions that all side payments have been made, or that institutional constraints are invariant, the tools of economics enable us to classify all three positions, 1, 2, and 3, as falling within the Pareto optimal or efficient set, and no one of these positions dominates the other. If individual preferences produce this set of results, we should be content with this and forego the essentially misleading searches for "philosophical implications" which simply are not there.

In this paper I have restated a position that I have presented in bits and pieces over almost two decades. Knight's favorite quotation from Herbert Spencer says that, "only by varied reiteration can alien conceptions be forced on reluctant minds." I hope that I have at least varied the reiteration sufficiently to avoid boredom. I would not presume to think that my own views on methodology would convince more than a minority of my professional colleagues, and I am under no illusions as to the continued dominance of the maximization paradigm in modern economics. Nonetheless, I think that progress has been made during the last twenty years. Game theory, after a series of disappointing attempts to work out optimal strategies for players, has shifted toward a more comprehensive, and more appropriate, consideration of solution concepts. Public choice has emerged as a subdiscipline in its own right, and one that is currently thriving, both within economics and in political science. But intellectual developments have perhaps been overshadowed in effect by the march of events. As persons, both from the streets and the ivory towers, observe modern governmental failures, they can scarcely fail to be turned off by those constructions which require beneficent wisdom on the part of political man. And they can hardly place much credence in the economist consultant whose policy guidelines apply only within institutions that embody such wisdom. Something is amiss, and economists are necessarily being forced to take stock of the social productivity of their efforts. When, as, and if they do so, they will, I think, come increasingly to share what I have called the contractarian paradigm.

As I have argued elsewhere (1964, 1969), economics comes closer to being a "science of contract" than a "science of choice." And with this, the "scientist," as political economist, must assume a different role. The maximizer must be replaced by the arbitrator, the outsider who tries to work out compromises among conflicting claims. The Edgeworth-Bowley box becomes the first diagram in our elementary textbooks; the indifference curve-budget line construction is relegated to subsidiary treatment. Eugen v. Böhm-Bawerk's horse traders are the basic examples, not the housewife who shops for groceries in the supermarket. Game theory, in its most comprehensive sense, becomes the basic mathematics for the professional, and solutions to n-person games replace the nth order conditions for maxima and minima. The unifying principle becomes *gains-from-trade*, not maximization. These principles merge, of course, at the level of the individual chooser's calculus, but they become quite distinct when attention shifts to the social interaction that we call "the economy."

Problems vs. Conflicts: Economic Theory and Ideology

By DUNCAN K. FOLEY*

This paper is an attempt to think about the relation between individualist economic theory and social reality. This relation arises in two ways: first, scientifically, in the problem of explaining real phenomena; and second, in policy, in the attempt to intervene to alter social reality in the light of economic theory. I believe that individualist theory has some grave problems in both these areas, and I will try to make some suggestions as to why it continues as a theory in the face of these problems.

To begin with, let me try to mark off what I mean by individualist economic theory, which I use in preference to "neoclassical," because neoclassical has so many different meanings for different people. I use individualist to describe the notion that social reality as we experience it is in its important economic aspects a reflection of certain tastes or preferences of individual people interacting through processes of choice with objectively given technological possibilities, whatever particular market or informational structures are thought of as mediating the individual choices.

I should emphasize that I am not here trying to criticize all the work at all levels done by people who believe in individualist economics, much of which does not, in fact, use the individualist theory in explanation. My exercise is directed at the "high" theory, perhaps best expressed today in mathematical general equilibrium theory and welfare economics, but which also underlies the work of the Chicago school of libertarian economics.

I.

Let me first take up what I feel is the fundamental scientific problem with individualist economic theory. The aim of scientific theory is to provide objectively verifiable explanations of phenomena. These explanations often involve a reference to invisible structures, the existence of which is posited by theory and the properties of which are deduced from observations given the theory. The theory of physics, for example, explains many of the properties of matter as derived from properties of elementary particles like electrons. Although electrons are invisible, we believe that they exist because the theory of physics explains so many phenomena, and because properties of electrons, such as mass and charge, can be inferred from many different experiments all of which agree. If the mass and charge of electrons were constantly changing, the electron would not itself be a very powerful explanatory structure.

If we are to take individualist economics seriously as a scientific (that is, explanatory) theory, then I think we must interpret the concept of "tastes" in the same way as we understand the concept of the electron. "Tastes" or "preferences" have to be taken as structures that have a material reality but are not directly observable. (I leave "technology" out of this discussion entirely.) Individualist economic theory proposes to explain phenomena by reference to tastes: "*X* happened in part because tastes were of a certain kind at the time." In this situation the explanatory power of the theory depends on identifying stable properties or laws of evolution of tastes. If tastes have no stable properties, then we learn nothing from an explanation that refers to them, and there is not much scientific reason even to believe in their material existence.

---

* Stanford University. I would like to thank Jens Christiansen, Partha Dasgupta, Paul David, Bridget O'Laughlin, Mike Spence, Dave Starrett, Joe Stiglitz and the Political Economy Seminar at Stanford University for discussions that helped me greatly in writing this paper. The ideas expressed are my own and I suspect that every person in the list above would disagree with at least one of them. In addition, I owe a considerable debt to many other people who also helped me on the road to the method of analysis and point of view that lie behind this paper. Among them are Mike Carter, Jack Gurley, Don Harris, Rod Jacobs, Chiranjib Sen, Gita Sen, and Sandy Thompson.

One would expect, then, that a central topic of individualist economics would be the identification of stable properties of tastes and of the laws that govern their evolution. It is striking that so little effort goes into this problem. It is not enough from this point of view to specify tastes that are consistent with a given set of demand data; some properties must be proposed that are stable over time and space or that evolve according to determinate laws. Measurements from different places and times would have to support each other directly or support a general law of tastes before we can begin to believe in tastes as an invisible but material determinant of social reality or find explanations based on tastes convincing.

I have come to doubt whether this program of establishing the material reality and properties of tastes can ever be carried out. Words like "prefer" and "choose," which are basic concepts of individualist theory, basically are used to express how a person subjectively experiences a situation. When one describes a situation as one of "choice" or "coercion," one is saying something about oneself rather than about the situation, since the same objective behavior can be experienced either as choice or coercion (or as "preference" or "habit" and so on). It seems to me questionable to include such subjective categories in objective explanations or descriptions of social reality. I think it is even an error to think of the problem as one of what determines tastes, that is, to seek objective factors that influence preferences, which then can be viewed as determining behavior. In this kind of scheme, the tastes themselves become superfluous. It seems rather that the question of how people experience a situation as subjects is a question on a totally different level from the question of what their behavior is.

Individualist economic theory appears to remain stuck in a particularly old-fashioned and unsatisfactory view that all human beings experience themselves as rational, calculating entities weighing certain ends against available means and experience their behavior as rational choice. Aside from the fact that this appears to be a postulate empty of explanatory power, it blinds individualist theory to the differences between people as they enter into relations with each other, for example, in the labor market, to the objective differences between the worker, who has nothing but his labor power and enters into the exchange in order to survive, and the capitalist, who controls his own and the worker's means of subsistence and enters into the exchange to make a profit. Both may (or may not) experience themselves as being rational decision makers, but that fact doesn't get us much further in understanding the nature of the relation they enter into (is it, for example, an equal or unequal relation, a cooperative or conflicting relation?) or the nature of society itself.

A particular example of the fallacies that individualist economics involves itself in, through its casual handling of the problems inherent in using subjective categories in attempts at scientific explanation, is that individualist economists will sometimes defend the reality of tastes by saying that they experience *themselves* as having tastes and making choices, so that they know that tastes exist objectively. This begs the scientific question, since what is required is not a private affirmation of belief, but a public demonstration that tastes are a real and powerful explanatory structure.

In passing I might suggest what seems to me to be the moral of this argument, which is that a scientific study of human society must begin by thinking about groups of people large enough to survive and reproduce themselves (just as the scientific study of ants might begin by viewing the anthill as the basic unit of analysis). In studying these groups it is sometimes necessary and always desirable to explain what subjective experience the people in the group will have of the material reality of their social existence, but we cannot expect to deduce much about social structure by starting from individual behavior.

II.

Let me now examine briefly the attempts to use individualist economic theory as a policy tool. The major concepts used in this endeavor are the idea of allocational efficiency and the idea of equity.

Economists often criticize and recommend policies from the point of view of allocational efficiency, that is, from a point of view that purports to represent the interests of the system as a whole. Antitrust policy, from this point of view, ought to be used to prevent deviations of price from marginal cost due to monopoly power. I gather that there is a good deal of frustration among antitrust economists because antitrust policy in reality does not systematically follow this goal. Some people are prosecuted even though their prices are close to marginal cost, and some whose prices are far above marginal cost are left alone. The same frustration reappears in most policy fields. Political decisions very often ignore the considerations of allocational efficiency.

Politics consists of struggles between groups of people. Things happen in politics because some particular group or coalition of groups becomes strong enough to enforce its own particular project on others. Allocational efficiency cannot be effective as a critical concept in influencing policy because it does not represent (in its own terms) the aims of any particular group. The idea that it could be effective arises because individualist economic theory represents government policy in an incorrect way, as the attempts of rational individuals to achieve collective ends, rather than as the tool which one class uses to enforce its desires on other classes.

The concept of equity as economists use it might at first glance seem to be a better way to approach policy problems. But I think it is also destined to be decoupled from politics. First, economists in talking about equity still try to make statements about properties of the whole society from outside it. Abstract considerations of equity are likely to move very few people politically. But, more important, classes in society struggle over their relations in a human and social sense: Who has power over whom in day-to-day life? When "equality" or "inequality" arise as forces in politics, they refer to equality as a characteristic of a social relation, and political struggles are most often undertaken to end a particular relational inequality. Unequal social relations (worker-capitalist, black-white, woman-man) always have the effect of producing unequal outcomes in the distribution of goods and services, but unequal outcomes are the symptom, not the disease itself. Equity in the sense that economists tend to use it errs in examining society at the level of distribution of goods and services alone. It ignores the relational inequalities that lie behind distributional inequalities, relational inequalities that I think can only be understood by looking through distribution to the process of production itself, and the unequal social relations that characterize production.

To sum up, then, the categories of allocational efficiency and equity are themselves the reason why individualist economic theory does not offer a reliable guide to or represent a powerful influence on real policies. The idea that it could or should have such an influence arises from an incorrect representation of social and political reality and government, one that ignores class differences and that understands government action as an attempt to achieve consensual ends rather than as always representing the particular interests of a victorious coalition.

III.

If individualist economic theory has serious problems as a scientific explanation, and if it also fails to reflect the real categories of political struggle and thus fails to influence political practice, why does it survive as a living body of ideas? I think that to answer this question we must turn our attention from the ideas themselves to the people who have them, that is, economists. (The argument of this section owes much to Louis Althusser's essay.)

In fact, we must address the question raised earlier: What is the relation between objective social reality and people's subjective experience of it? People generally have definite ways of perceiving social reality which is sometimes called ideology. More important than the particular content of people's view of the world are probably the categories by which they order their experience. A pertinent example is whether a person perceives human society as a unitary thing in itself, surviving through the medium of individuals, but fundamentally molding individual behavior (the anthill), or whether the person perceives individuals as the fundamental and natural unit and society as an aggregation of individuals (the ant). I argue that the way a particular group of people will image reality and their relation to it, its ideology, depends on the actual location of the group in the social division of labor, but not in a simple, direct way.

In considering individualist economic theory as the ideology of economists, it is important to think of ideology as a tree-like thing. Certain categories and understandings are common to everyone (or almost everyone) in a given society at a particular historical moment. This common system of ideas is sometimes called "dominant ideology." Individualism seems to be such a category in our society today. But there will be variants or elaborations of these common understandings which will be the peculiar preserve of certain groups that occupy a certain place. Individualist economic theory, insofar as it is individualist and rationalizes capitalist social relations in terms of individual interests, partakes of the dominant ideology and tends to reinforce the reproduction of capitalist and social relations.

But I think it is a mistake to understand the ideas that are specific to economists (for example, allocational efficiency) as direct apologies for capitalism. For one thing, individualist economic theory as an apology for capitalism, or as a mystified expression of the interests of the capitalist class, is hopelessly out of date. Very few people can bring themselves to believe in the competitive model as an accurate representation of reality for very long (say, longer than the time it takes to write an exam). As a guide to policy, individualist economics tends to come up with policy recommendations (deregulation, for instance) that are at variance with the expressed interests of dominant capital (and are therefore futile).

I suggest that individualist economic theory as a particular variant of the dominant individualist ideology continues to live because it represents the relation between social reality and the economist in a way that helps economists come to terms with their own fate. In addition to misrepresenting real social relations (representing unequal relations in production as equal relations of exchange, for instance) individualist economic theory creates an image of the economist as a technician standing outside social reality as a system, ready to intervene on behalf of the interest of the system as a whole. This image is imaginary and defective, because society is not a "system" in the sense of an object designed for some particular purpose, but a process of struggle. Thus there is no sense in which there is an interest of society as a whole, only the interests of particular classes or groups. The organization of society is not a technical question because institutions are not designed to perform certain functions; they are rather molded historically out of a process of struggle and compromise, so there is simply no place for a technician to intervene from outside to adjust or improve them.

Despite its defects as a representation of the situation, this image helps economists keep going in their real position, which is as a part of social reality and social struggle, not above it. The image distances the economist from what is going on. It is common for economists to view what is actually happening as a series of "mistakes" (that is, deviations from allocational efficiency or equity) and therefore in a sense not completely real (because things could have happened another way). The economist can take up a stance of humorous or sorrowful detachment toward what is happening.

The real place of economists in the social division of labor is as a part of the state apparatus (whether we are directly paid by the government or not) charged with collecting and ordering certain data about the economy, analyzing the data and trying to use it (usually without the help of any theory beyond an empirical faith in extrapolation) to predict consequences of policies, taking part in debates over state policy, and reproducing ourselves as a class of specialists. These activities are in most cases in support of the ruling coalition of class interests at any moment.

The practice of economists, I argue, is a practice of intervention on a particular side in political struggles. Individualist economic theory represents the economist as intervening, but not on any side—rather on behalf of the system as a whole. This contradiction is overcome in most cases by a logical leap, which identifies the real, actual government (if not the specific administration of the moment) with the interests of the whole society. This is a leap because government, like the market, money, corporations, and universities, grows out of historical struggle and has an objective reality that has nothing to do with the somewhat metaphysical notion of the interests of society as a whole. This leap is supported within individualist theory by models of government as a supplier of public goods or as an umpire in market failure situations—models which elaborate on the necessary leap without bridging the gap and which are themselves clearly defective representations of reality.

What is most striking to me about this situation is that economists in most cases enter the field critical of society and eager to understand its problems. We end in most cases by supporting the dominant class coalition and rationalizing or explaining away conflicts and contradictions in the society. Individualist economic theory has more than a static existence. It is a road of personal compromise that each human being who becomes an economist travels as social reality molds his or her practice. If we understood this more clearly about our own lives, we might not be so likely to accept misrepresentations of an individualist nature of other people's lives. People who become critical of social institutions and practice often sense that they need a critique or analysis of society as a whole to be successful in changing it. Individualist economic theory, which represents the society as a whole in mystified terms, is what you will be offered if you set out on that quest in our society.

I think that this is not a satisfactory state of affairs. The ineffectiveness of policy economics is a symptom of a deeper bind that economists are in. Frustration over the irrationality of regulatory policy or antitrust legislation or whatever is the way economists experience their own dependence on the dominant class coalition. That individualist theoretical categories like allocational efficiency and equity do not correspond to the effective categories of political struggle is a consequence of the ideology in which economists live and are able to function. It seems unlikely that a change in the content of economic theory can resolve this bind, which is personal and social as well as theoretical. I suggest instead that we must change our mode of response to social reality. Policy economics now consists of rhetorical, judgmental, "objective" written or verbal commentary on social problems. I think we must engage ourselves directly and consciously in the struggles of society on one side or another. Once our practice changes in this direction and we begin to experience ourselves as participants in social struggle, there will be a revolution in economic theory, but I cannot see how such a revolution can come first or by itself.

Law and Economic Theory: An Economist's View

By Alvin K. Klevorick*

Taking stock of the realized and potential contributions of any area of intellectual endeavor is a difficult task. The assessment process is even more difficult if the field is relatively young and if it is interdisciplinary. Such is the case with law and economic theory. In this paper, I will attempt to give my view, as a participant in the law and economics enterprise, of the types of contributions economic theory can make to law—to legal decision making, to the study and development of legal doctrine, and to the study and analysis of legal structure. These views should be understood as simply *an* economist's view. I make no attempt to describe what must be a wide spectrum of views held by economists working in the area, and I certainly make no pretense to present the views of the lawyers engaged in this joint enterprise.

The first kind of contribution an economic theorist can make in law arises when economic concepts become important in understanding some aspect of a particular legal case. Although the overall question raised by the case may not be economic in nature, at some point an understanding of how markets work, how markets value commodities, services, and assets, and how individuals interact in their economic roles may become critical in deciding the ultimate disposition of the case. One can take an example as basic as the valuation of a capital asset. Suppose, for example, that through some set of circumstances (which we will not inquire into now), A has destroyed B's widget-making machine. The latter has no sentimental attachment to his machine, but values it only for the widgets it enables him to produce and sell. Without inquiring how the court reaches this position, suppose the court decides to award B an amount in damages equal to the value of the machine A has destroyed. An economist armed with his understanding of how markets value capital assets should be able to help the court in deciding the appropriate amount for B to receive in damages, given the court's decision that B should be compensated for the loss he has incurred because of A's destruction of the machine. An economist should also be able to help the court if B returns, as some real-world plaintiffs have, and asks for compensation, *in addition to* the amount the court has already awarded him, for the loss of profits he will incur until he can replace his widget-making machine with the new one he has just ordered.

In such a situation, the economist essentially plays the role of technician. He takes the problem facing the legal decision maker framed the way the legal decision maker has posed it, and he brings his expertise to bear in dealing with a specific part of the case. The economist draws upon his understanding of the way in which particular functions of society are performed, and he uses that understanding to shed light on specific issues in a given case. It is not a terribly imaginative role, but it is undoubtedly a terribly important one.

The second type of contribution an economist can make to law might be described as the economist in the role of "supertechnician." Once again, the economist takes the problem as set by the lawyer or by the legal decision maker, but in this instance the entire structure of the problem area has economic roots. The objectives and design of the institutions and doctrine are explicitly stated in economic terms, and the economist is called upon to evaluate and give advice about the best ways to achieve the specified objective(s). Most of the traditional areas of interaction between law and economics would fall, I think, into this category. They include, for example, the areas of antitrust law, public utility regulation, and labor law. When the issues at hand concern the most efficient way, or at least more efficient ways, of structuring an industry or a sector of the economy or the relationship between economic agents, the question comes ready-made for the economist to make an important contribution.

---

* Yale University.

One particularly important function the economist can play in his role as super-technician is to question whether the legal decision maker's general approach in a particular area actually helps to achieve the end the legal decision maker has in mind. For example, putting aside for the moment the multiplicity of reasons and rationales that might lie behind the institution of public utility regulation, suppose the legal decision maker asserts and believes that the primary objective of a system of public utility regulation is efficiency in the economist's strictly defined sense. The economist should be able to point out the kinds of characteristics commonly associated with natural monopoly and the kinds of characteristics which might suggest the need for special concern about the efficient functioning of an industry. He can help to focus the discussion to see whether the industry for which regulation has been proposed is indeed a natural monopoly. If the answer is yes, the economist can—and should—then suggest to the decision maker the variety of possible responses to the natural monopoly situation, responses ranging from having the natural monopoly privately owned and unregulated, to the general type of public utility regulation we have today, to an alternative type of regulation, or, finally, to public enterprise.

One thing the economist should do is provide the decision maker with an evaluation of the advantages and disadvantages of each of these alternative approaches. He should frame the discussion so that it encompasses not only the direct impacts each of these systems will have on the efficiency of the sector or industry whose regulation is being contemplated, but also the side effects or indirect effects that such regulation might have on this industry and its consumers and on other industries and other consumers in the economy. It would also seem to be incumbent upon the economist to try, to whatever extent possible, to indicate the income- (or wealth-) distributional impacts of such a regulatory policy. For although we have assumed (for the sake of this discussion) that the averred and true goal of the decision maker's use of regulation is to achieve efficiency, there are undoubtedly some tradeoffs between efficiency and distribution in the choice of a response to the natural monopoly problem, and the economist is particularly well suited to the task of pointing out what kinds of tradeoffs exist. Of course, while most of my discussion is concerned with the role of the economic theorist, the kinds of judgments that would be important, indeed critical, in such a balancing act are empirical judgments (and empirical guesses if hard data do not exist concerning these alternative costs and benefits). But even the theorist can help, and should help, to focus the discussion at the level of a comparative institutional analysis—a comparison of the alternative systems available for trying to achieve the given objectives.

In the context of this role as supertechnician, the economic theorist can also have a considerable input in designing the particular legal structure that is eventually chosen to cope with the given legal problem. For example, in the public utility area the economic theorist may be able to indicate which kinds of regulatory structures are most likely to achieve the goal of efficiency. He would be able to delineate, from an efficiency point of view, which kinds of issues are best handled using automatic adjustment clauses and which types of issues are best thrashed out in an alternative procedural setting.

In sum, when the economic theorist acts as a supertechnician for the lawyer, he draws on his expertise in analyzing a problem posed by the lawyer, just as he did in the role I described as economist as technician. But now the problem he is addressing is in its own terms economic in nature.

The third role I see for the economic theorist in the joint enterprise of law and economics is one that has come to flourish quite recently. Put briefly, it envisions the economist or economic theorist as the propounder of a new vocabulary, a new analytical structure for viewing a traditional legal problem. In contrast to the economist's approach in the first two categories of interaction I discussed, in this third role he no longer takes the problem as framed by the lawyer. Rather he takes the general problem area with which the lawyer is concerned—say, torts, or property, or procedure—and poses in his own terms—that is, in economic terms—the problem he sees the legal structure or legal doctrine confronting. He provides, thereby, a different way of looking at the legal issue which yields alternative explanations of how current law came to be what it is and new proposals for new law.

In the area of torts, for example, some economic theorists have posed the problem facing society as minimization of the expected social costs of accidents, taking account of: the costs incurred when accidents occur and the probabilities that such accidents will occur; the relationship between those accident costs and probabilities and the steps people take to avoid accidents; the costs of the resources devoted to avoiding accidents; and the costs of any administrative structure used to make decisions about the optimal level and allocation of these several kinds of costs among members of society. Economic theorists have used this type of framework to discuss and evaluate the traditional negligence rules, to provide a critique of the fault system of accident law, and to evaluate new proposals for automobile accident law, for example, no-fault plans. To take another example, the design of a system of civil procedure, criminal procedure, and judicial administration has been formulated by some lawyer-economists as the problem of minimizing the sum of the social costs of resources devoted to such procedural systems and administrative mechanisms plus the error costs of those procedures. This framework has then been used to evaluate various specific aspects of procedure and judicial administration: for example, the discovery rules of the Federal Rules of Civil Procedure, the bail system, the existence of plea bargaining, and the use of the jury.

This third role is probably the most exciting one the economic theorist can currently play. This form of interaction with the lawyer appears to be the most creative and the most challenging. Hence, it is interesting to ask whether particular kinds of problems confront the economist when he presents a new vocabulary or a new structure for analyzing a legal problem. I think two such problems are particularly important—one arises from a constraint imposed by the economist's tools while the other is a limitation imposed by the lawyer's formulation of the problem area.

The constraint imposed by the economist's tools is perhaps seen best in the context of a concrete example. Consider the problem of designing a set of liability rules for accident law in the world in which we live today. It should be clear that any attempt to analyze reality, to make meaningful statements about it, requires some abstraction from the richness of the phenomena being studied. The lawyer's world view is an abstraction just as the economist's is. The economic theorist's approach is to begin with the simplest possible model which captures important structural elements of the problem and to analyze that model as carefully as possible. As a theorist, I think this is a wise strategy. Having analyzed the simplest model, one might then proceed by relaxing some of the unrealistic assumptions which made one's first construction so tractable. For example, one might assume at the first step that all accident costs are, in fact, known to all parties making decisions about what levels of care to exercise. The second level of analysis might involve a relaxation of that assumption and a recognition that some parties will not be fully aware of these costs. The single (certain) values individuals attached to accident costs in the first model might now be replaced by subjective probability distributions people have about the accident costs that will be incurred.

Now suppose that in the simplest model several different liability rules would each yield the full-information social optimum by leading individual decision makers to attain the social-cost-minimizing combination of care levels. As one relaxes the assumptions of the model, the set of liability rules that will achieve the social optimum will undoubtedly become smaller. Further relaxations of the original assumptions—further gropings toward a more realistic representation of the world and people's decision-making processes—will undoubtedly reduce even further the number of liability rules that yield the social-cost-minimizing solution. Indeed, it is most likely that before long the set of socially optimal liability rule structures will become empty. In short, there is no first-best solution in the real world or, for that matter, in the most complicated, yet tractable model we may construct.

The question then is: If the economic theorist is going to use his theoretical analysis to make policy recommendations, how should he proceed? It would be tempting simply to consider those policies that were socially optimal in, say, the next-to-the-most complicated model he had. The problem with this, of course, is that the order in which the theorist relaxes his original assumptions to arrive at the most complicated model he analyzes—that is, the path that leads to the continually shrinking set of socially optimal policies—has no particular normative justification. He could follow an alternative complicating path which might well generate an alternative second-best policy.

The realization that we are making decisions in a second-best (indeed, an *n*th-best) setting does not imply that the theorist's models and analyses should be dispensed with or ignored. Nor should the second-best nature of the decision problem be used by the economist as an excuse for avoiding statements of a policy nature. To evaluate alternative policies, however, the theoretical model must be used in conjunction with careful, empirically rooted judgments (guesses?) about which of the theorist's original simplifying assumptions are most likely to affect the applicability of his model's results. And the order in which the theorist relaxes these assumptions in building successively more realistic models need not reflect the empirical importance of the various assumptions. Hence, there is no reason to evaluate second-best policies by simply removing, in reverse order, the complications introduced to obtain the most realistic model.

The theorist can contribute in two ways to the comparative institutional analysis the law and economics enterprise should produce in such situations. First, by providing a new and different way of looking at the traditional legal issue, he will, hopefully, provide clarification and new insights into that issue. Second, he will provide an indication of the kinds of empirical guesses that are needed in order to use his theoretical investigation for policy formulation in the world in which lawyers actually operate.

A different, but equally important, difficulty arises when the economic theorist provides a new vocabulary for a problem which the lawyer poses in a form not really amenable to economic analysis. While the theorist might be tempted to show how his analytical structures can be applied to particular issues in such areas, it is simply the case that his tools are inappropriate to the overall task. I have particularly in mind those areas in which lawyers or legal scholars have framed the legal question in process-oriented rather than outcome-oriented terms, that is, as a question about how a decision will be made rather than about what the decision will be. Questions of institutional competence, questions of whether a particular issue is one that should be taken up by legislatures or by courts, are questions which are not easily comprehended within the economist's framework.

The issue as posed by the lawyer in such cases does not seem to be rooted in the search for some neatly defined social optimum—be it the maximum of a social welfare function or the minimum of some social cost function. The problem is not framed as the search for an *efficient* way of reaching a decision or deriving a structure of rules, but rather as the determination of the "*appropriate*" way of reaching a decision or the "*appropriate*" institution to use to decide the particular issue. And the question of appropriateness is most likely to be resolved by appeals to history, to political theories of democracy, and to sociological theories of the role expectations of different members of the society. This is not to say that the economist's analytical structures cannot provide some help in examining these questions. In particular, when the lawyer appeals to political theories of democracy to help decide which institution is appropriate, he may well benefit from consideration of voting models and other models of the political process developed by theoretical economists and political scientists working in the area of public choice. The point simply is that when the lawyer or legal scholar has framed the problem in process terms, focusing on the appropriateness of one institution rather than another to perform a particular function or to make a particular decision, the lawyer is least likely to be receptive to the economist's vocabulary, rooted as that is in terms of a search for efficient structures, for efficient decision-making processes, and the like.

To be sure, questions of relative institutional competence can be stated in economic terms. One can talk about which institution has a comparative advantage in performing which function. We can ask whether courts or legislatures are "better" at developing liability rules, whether courts or administrative agencies are "better" at determining the value of a fair rate of return to a public utility, whether legislatures or courts are "better situated" to decide which interests are fundamental and which interests are not (alternatively, which wants are merit wants), or whether the judiciary or the legislature or the executive is the appropriate institution to decide if and when prior restraint over publication should be exercised. One can use the terminology of economics and talk about the costs and benefits of using one institution rather than the other. But when the legal scholar has posed the problem in process terms, the analytical structure the economist offers for the given legal issue may not prove very helpful to the lawyer.

Let me try to illustrate this point with two examples. The first concerns freedom of speech. I believe that the economist (or the lawyer-economist) can contribute to our understanding of and deliberation about the appropriate scope for freedom of speech by taking seriously a concept which many Justices and legal scholars have invoked in their discussions of First Amendment freedom of speech issues: the marketplace of ideas. The economist can contribute by taking such references to the marketplace of ideas as something more than simply rhetoric—as, instead, an attempt to invoke what appears to the lawyer to be an appropriate analogy. Then, by bringing to bear his understanding of the ways in which markets work, of the potential sources of market failure, and of the possible responses to such market failures—all within a comparative institutional analysis framework—the economist may provide interesting observations (at least in efficiency terms) about possible arguments justifying and opposing limitations on freedom of speech in specific situations.

Exploiting the analogy of the marketplace of ideas, the economist can, I believe, provide a clarifying view of some aspects of the development of legal doctrine in the First Amendment area, for example, "the clear and present danger" test and its development and application in the case law. But suppose the legal scholar's formulation of the First Amendment issue takes the form of the question: Which institution or which branch of government is the *appropriate* one to determine the scope of First Amendment rights? For example, suppose that the majority of a duly elected legislature believes that advocacy of a particular political philosophy poses an imminent danger to the nation. The legislature enacts a statute making advocacy of the particular political views a criminal act. The legal scholar might ask: How deferential should a court be to the legislature's judgment if a suit is brought challenging the law? The economist's analysis and interpretation of the development of judicial doctrine may not be very helpful to the lawyer or legal scholar in answering this question.

The second example concerns whether juries in criminal trials should be representative, whether they should represent a cross section of the community. Here I think the economist can help in evaluating how effective representativeness of the jury is in furthering performance of the jury's fact-finding function. He can suggest and explicate the analogy between the selection of a jury and the selection of a portfolio of assets by an investor. Pursuing this analogy, with the consequent delineation of the similarity between representativeness of a jury and diversification of an investment portfolio, the economist can draw upon portfolio selection theory to suggest the kinds of circumstances under which representativeness would make the jury a more effective fact-finding body and the types of situations in which representativeness would not serve that end. I think that introduction of the economist's vocabulary in this discussion is interesting and helpful. But if the question of jury representativeness is framed not in the instrumental sense of achieving some further objective, like fact finding, but rather in more process-oriented terms, which would have a representative jury as the *appropriate* type to decide criminal cases, then the economist's vocabulary is much less likely to clarify and illuminate the issues for the lawyer.

We come now to the question of what happens after the economist has proposed a new vocabulary for viewing a traditional area of legal concern. One possibility, of course, is that the new vocabulary will simply be rejected, and I have tried to indicate at least one reason why that may occur. A second possibility is that the new vocabulary, the new way of viewing the problem, will come to displace the old. While I regard this outcome as highly unlikely, it nevertheless suggests the major danger that I see, and that I hope will be averted, in the application of economic theory to legal problems: namely, a type of intellectual imperialism on the part of the economic theorist or the lawyer-economist. It is the danger that, having created or at least suggested a new vocabulary for viewing the legal issue, the economic theorist or the lawyer-economist will develop—or even worse, try to generate in others—a form of tunnel vision in which he sees the new vocabulary as the only "reasonable" one for viewing the area. While I firmly believe that economics can make a contribution to law and that economic theory in particular can make such a contribution, I do not believe that the analytical grid the economic theorist imposes on the legal problem is the only one worth examining.

The most likely result of the economist's suggestion of a new analytical structure is the coexistence of his new approach to the problem with other, perhaps more traditional, approaches to it. For example, thinking of civil procedure as designed to minimize the sum of the direct costs and error costs of procedure will come to coexist with an understanding of certain elements of procedure as generating or guaranteeing a sense of fairness in the way our legal system operates. Our system of tort law will be understood both in terms of minimization of the social costs of accidents and in terms of noneconomically based ideas of causation and reciprocity.

Economic theory's contribution to law is likely to be greatest if, in proposing new analytical structures for traditional legal issues, the economist or lawyer-economist takes a constructive eclectic view and welcomes the contributions other social scientists may be able to make to our understanding of these areas. For psychologists, historians, sociologists, and others can also suggest new and potentially useful approaches to legal issues, approaches which will undoubtedly complement the economist's with its relative inattention to a variety of questions—like historical development, the formation of individual and social tastes, and so on. The economic theorist's new formulation essentially provides a new metaphor for viewing the particular area of legal concern. But the economist's suggested metaphor is only one among many, and in attempting to understand, to analyze, and to aid in the development of the law, an approach which draws upon the variety of ways the several social sciences analyze human behavior is likely to be the most helpful and the most successful.

SOURCES AND USES OF PANELS OF MICRODATA

The National Longitudinal Surveys: New Vistas for Labor Market Research

By HERBERT S. PARNES*

For nearly a decade the Ohio State University Center for Human Resource Research and the U.S. Bureau of the Census, under separate contracts with the U.S. Department of Labor, have been engaged in the National Longitudinal Surveys (*NLS*) of labor market experience. Four subsets of the United States civilian population are being studied: middle-aged men who at the inception of the study were 45 to 59 years of age; women 30 to 44 years old; and young men ("boys") and young women ("girls") between the ages of 14 and 24. A rich data bank is being accumulated that has already served as the basis for thirteen comprehensive research monographs and over seventy-five specialized studies completed by staff members of the Center for Human Resource Research and other researchers throughout the country.[1] The purpose of this paper is to describe the nature and availability of the *NLS* data and to illustrate the more or less unique kinds of analysis they make possible.

I. The *NLS* Data

The cohorts comprising the *NLS* were chosen because each is confronted by special labor market problems. In the case of the men, for example, skill obsolescence, deteriorating health, declining vigor, or age discrimination may lead to premature withdrawal from the labor force or other manifestations of labor market difficulty. The special problems of the women are those attending reentry to the labor force after periods of absence during which there may have been a deterioration in both vocational and labor market skills. The two groups of youth face the difficult process of occupational choice and the period of accommodation to the labor market during which turnover and unemployment rates are high.

For each of these four population groups, a national probability sample of approximately 5,000 individuals was drawn by the Census Bureau by a method analogous to that used in the Current Population Survey (*CPS*). However, in order to permit statistically reliable estimates for blacks, the sampling ratio in predominantly black neighborhoods was three to four times as high as in white areas. As a result, each sample contains roughly 3,500 whites and 1,500 blacks.

A very useful aspect of the sampling design is that many of the households yielded more than one respondent, frequently across cohorts, and it is possible to relate to any given respondent other respondents who were selected from the same household. To illustrate, there are 567 households with at least one subject in the men's sample and one in the women's, most of these representing husband-wife combinations. Similarly, there are about 900 man-boy and 800 man-girl combinations; 1,400 woman-boy and 500 woman-girl combinations; 1,800 boy-girl combinations; and in excess of 300 households in which man, woman, and at least one youth are included in the *NLS* samples.

* Professor of economics and research associate, Center for Human Resource Research, The Ohio State University. I am grateful to my colleagues Carol Jusenius, John Grasso, Gilbert Nestel, and Steven Sandell for useful comments on a preliminary draft.

[1] For a complete bibliography, see the *National Longitudinal Surveys Handbook*, beginning on p. 41.

Members of each sample have been interviewed periodically by *CPS* enumerators, using schedules prepared by the Center for Human Resource Research. Originally planned to cover a five-year period, the surveys have been so successful and attrition so small that they have been continued beyond the originally planned expiration dates. As of the end of 1974, the men had been surveyed in 1966, 1967, 1968 (mail), 1969, 1971, and 1973 (telephone); the women in 1967, 1968 (mail), 1969, 1971, 1972, and 1974 (telephone); the boys annually between 1966 and 1971 and by telephone in 1973; and the girls annually between 1968 and 1973. As of the most recent interviews, attrition had claimed only 21 percent of the original sample of men, 15 percent of the women, 23 percent of the boys, and 14 percent of the girls. In the case of the men somewhat over half of the losses were attributable to death. Among the boys, induction into military service accounted for much of the attrition between 1966 and 1971, but respondents reentered the sample as they returned from service; the number of completed interviews was slightly greater in 1973 than in 1971.

In a brief paper it is possible only to hint at the variety of data that have been collected over the years of the *NLS*.[2] In most general terms it may be said that information has been obtained on virtually every aspect of labor market experience—in abbreviated form for that portion of the individual's career prior to the initial survey and in considerable detail for the period covered by the surveys. In addition, information has also been accumulated about factors that are hypothesized to influence labor market behavior and experience, e.g., health, education and training, family structure, a variety of attitudes, and several characteristics of the local area in which the respondent resides. Many of the questions included in the interview schedules are common to all four cohorts, e.g., those relating to current labor force and employment status, employment experience during the period since the previous survey, health condition, training experience, job attitudes, and sources of income and wealth. On the other hand, some are unique to one or two cohorts, e.g., retirement expectations and attitudes for the men; detailed educational histories for the boys and girls, including mental ability test scores obtained from the high schools they attended; and child care arrangements and preferences for the women.

II. The *NLS* Public-Use Files

Publication of the initial reports on the *NLS* generated numerous inquiries about the availability of the data, in response to which the Census Bureau agreed to prepare public-use versions of the data tapes very similar to those which they were preparing for the Center for Human Resource Research. These tapes had a number of undesirable characteristics—e.g., alphabetic codes—that made them difficult to use for many types of analysis. Thus, all purchasers had to perform "cleansing" operations that were more or less identical to those undertaken by the Center to make the tapes operational. In order to eliminate this duplication of effort, the Center agreed in 1973 to assume the responsibility for revising those tapes already released by the Census Bureau and for preparing all subsequent public-use tapes.

---

[2] A detailed description is contained in the *National Longitudinal Surveys Handbook*.

By the end of 1974, cumulated data files through the 1971 surveys for the men and women, the 1970 survey of the girls, and the 1969 survey of the boys had been released by the Center, each at a price of $300. It is contemplated that an updated file containing the data from each additional survey will be ready for release approximately one year after the Center receives the relevant tape from Census. On this basis, cumulative records through 1973 for the men, 1970 for the boys, 1971 for the girls, and 1972 for the women are expected to be forthcoming in 1975, each at the $300 price mentioned above. This price includes the computer tape(s) in any one of twelve forms desired by the purchaser, two copies of the documentation, and for those who wish it, a copy of the documentation on computer tape.

The documentation that accompanies the *NLS* data files is designed to facilitate access by users to a large and complex body of data, e.g., 2,540 variables in the case of the men's surveys through 1971. A very useful component is the *KWIC* (key word in context), an alphabetic index that provides a convenient means of identifying variables and locating them in the code book. For each variable, the code book displays a frequency count and indicates the interview schedule item number(s) from which the variable was derived.

As of the end of 1974, 69 data files had been ordered by 37 researchers or research groups throughout the United States. However, these figures understate the extent of utilization of the *NLS* data, since the Census Bureau had sold over 125 individual survey tapes to a total of 28 researchers prior to the revision of the files by the Center. Moreover, an unknown number of "bootleg" tapes are in use, having been copied from those purchased either from the Census Bureau or the Center. Under its contract with the Department of Labor, the Center serves as a central clearinghouse for research utilizing the *NLS* data. Since the spring of 1974 it has published a quarterly *Newsletter* that catalogues recent research reports and research in progress based on *NLS* data. Also included is information concerning release dates of future data files and errors that may have been uncovered in those already issued. The *Newsletter* is mailed to all known users of the data files and to other members of the research community who request it.[3]

III. Research Potential

Although a substantial portion of the data from the *NLS* has not yet become available for analysis, enough work has already been done at least to illustrate the potential contribution of the project to a better understanding of the operation of labor markets and of factors affecting the labor market experience and behavior of individuals. The richness of the *NLS* for labor market research stems largely from the longitudinal character of the data, from the inclusion of a variety of social-psychological variables along with detailed work histories, and from the existence of multiple-respondent households.

Perhaps the single most important contribution of longitudinal data is that they facilitate the identification of causal relationships that cannot confidently be identified in any other way. Take, for example, the relationship between attitudes and behavior. In cross-sectional data such relationships are ambiguous, since one cannot be certain whether the attitude produces or reflects the behavior. Does job dissatisfaction lead to turnover, or does an association between the variables simply mean that individuals who quit jobs are likely to rationalize their behavior by reporting (retrospectively) that they were unhappy? When attitudes measured at one point in time can be related to *subsequent* behavior, such ambiguity disappears. The *NLS* data for middle-aged men have clearly demonstrated that the degree of job satisfaction *predicts* the likelihood of a voluntary job separation and that a commitment to work in general, as well as satisfaction with one's particular job, decreases the likelihood of early retirement (Parnes et al., chs. 3 and 5).

---

[3] Requests should be addressed to Center for Human Resource Research, 215 W. 11th Avenue, Columbus, Ohio, 43201.

To cite another example, Thomas Mahoney's analysis of cross-sectional data found a relationship between the attitudes of married women toward the "proper" role of wife and mother and their labor force participation, but G. Cain (pp. 39–40) has criticized such evidence for its circularity. The ambiguity would appear to be removed by the *NLS* data shown in Table 1, which relates the attitudes expressed by young women *before their marriage* to their labor force activity after marrying and bearing children. Those who had expressed the most permissive attitudes toward labor market activity by young mothers in 1968 were, *ceteris paribus*, significantly more likely to be in the labor force three years later than those with less favorable attitudes.

TABLE 1—ADJUSTED LABOR FORCE PARTICIPATION RATES OF MOTHERS 17–27 YEARS OF AGE, BY PREMARITAL ATTITUDE TOWARD EMPLOYMENT OF MOTHERS OF YOUNG CHILDREN, 1971

Attitude[a]	Number of Sample Cases	Adjusted Labor Force Participation Rate[b]	
Opposed	104	33.5	
Ambivalent	123	31.8	
Favorable	150	48.7	
Total[c] or average	381	38.8	
F-ratio			3.59*

[a] Based on scores on a series of questions exploring respondent's reaction to propriety of work by women with preschool-age children under alternative specified circumstances.

[b] Adjusted labor force participation rates obtained from multiple classification analysis with three explanatory variables in addition to attitude: race (white, black); education (0–11 years, 12 years, 13+ years); husband's income (under $5,000; $5,000–$7,999; $8,000 or more).

[c] Total includes four cases for which attitude was not ascertained.

* Significant at $\alpha \leq .05$.

Source: National Longitudinal Surveys.

Social psychological variables in the *NLS* have also been shown to exert an influence on earnings or occupational status independent of conventional human capital variables. For example, Paul Andrisani and Gilbert Nestel report that a belief in the efficacy of individual initiative contributes to the level of average hourly earnings of middle-aged men (Parnes et al., ch. 6). As another illustration, Parnes and Andrew Kohen have shown that young men who manifested superior occupational information in 1966 enjoyed greater earnings and higher occupational status two years later than their more poorly informed counterparts.

The usefulness of longitudinal data in clarifying causal relationships is, of course, not confined to instances in which one of the variables is attitudinal. For example, finding that the receipt of training by middle-aged men between 1966 and 1971 was associated with a net earnings advantage in 1971 (controlling for such other factors as education, health, and region of residence) Arvil Adams went on to demonstrate that the trainees-to-be had already enjoyed higher earnings in 1966 (again controlling for the same variables) (Parnes et al., ch. 2). Thus, training was found to be a selective process, presumably attracting the more highly motivated or otherwise more productive individuals. To put the matter differently, some part of what would doubtless have been identified by a cross-sectional analysis as training's contribution to earnings was found to have reflected an incompletely specified model—i.e., the failure to control adequately for factors associated both with earnings and the probability of receiving training.

Quite aside from its longitudinal character, the *NLS* data provide a particularly rich data source for exploring the extent and nature of labor market discrimination. As is well-known, the principal difficulty in this type of research lies in being able to control for all factors that affect productivity. The social-psychological variables that exist in the *NLS*, along with measures of human capital and detailed records of labor market experience, provide a better basis for doing this than most other bodies of microdata. The question of racial discrimination can be pursued within each of the cohorts, while the issue of sex discrimination can be studied on the basis of the data for the girls and boys. A limited amount of research on racial discrimination based on *NLS* data has already been reported by Kohen, Robert Flanagan, and Robert Hall and Richard Kasten.

As has been indicated above, the existence of substantial numbers of multiple-respondent households in the *NLS* affords unusual research opportunities stemming from the fact that detailed information has been obtained directly from each individual relating to personal characteristics, to labor market behavior and plans, and most importantly to attitudes. One use of such data is in methodological studies of the consistency of response to factual questions by different members of the same family (e.g., Michael Borus and Nestel). Second, a number of fascinating questions may be raised concerning the consistency of various types of attitudes among family members, e.g., the relationship between the educational aspirations of a young man and the aspirations for him expressed by his father. Third, the extent to which the attitudes and/or labor market behavior of one family member affect the current or subsequent characteristics or behavior of other members of the family may be explored. An interesting illustration is Belton Fleisher's study of the effect of a mother's allocation of time between home and market production on the human capital of her son(s). Most models of labor supply assume that the behavior of individuals is guided by a desire to maximize the utility of the entire household, but the absence of data has generally prevented empirical research from making such a model operational. The multiple-respondent household in the *NLS* should go a long way toward eliminating this deficiency, albeit with a relatively small and perhaps nonrepresentative sample.

Another category of research that may be served by the *NLS* data must at least be mentioned—the study of gross changes in a variety of educational and labor market variables—e.g., enrollment status, labor force and employment status, occupational and industrial affiliation, etc. A very important line of investigation subsumed in this category relates to changes in income. A beginning has already been made in the analysis of the extent and sources of income instability among the men and boys (Kohen, Parnes, and Shea), but this will doubtless be expanded to additional cohorts and over longer periods of time as the studies continue.

Finally, an important contribution of the *NLS* stems from the opportunities they afford for the replication of studies. The availability of identical data for a number of years allows a researcher to examine the consistency over time of relationships or estimates derived from data for a single year. Also, the widespread distribution of the public-use tapes permits researchers to attempt to replicate the findings of complex research designs and methods of analysis employed by their colleagues. Both of these processes should enhance the confidence with which research findings may be accepted.

IV. Conclusion

The National Longitudinal Surveys permit a more effective investigation of a number of types of questions relating to the operation of labor markets than has hitherto been possible. The types of research that have already been based on the data illustrate the potential, and a good portion of future research will doubtless be similar to that already executed, but will have the advantage of additional waves of data as they become available. If, as now appears likely, the surveys are continued to cover a full decade, additional types of research will be possible. For example, by 1976 a third of the sample of men will be at or above the conventional retirement age of 65 and an even larger proportion may have actually retired, which will permit an analysis of the relationship between retirement expectations and actual retirement behavior. Similarly, by 1976 and 1978, respectively, the substantial proportions of the boys (60 percent) and girls (50 percent) who were enrolled in school at the time of the initial survey will, with few exceptions, have left school, permitting comprehensive analyses of the process of adjustment to the labor market. In any case, the *NLS* data base will almost certainly provide a fertile field for labor market research for many years to come.

Using Survey Data from the University of Michigan's Survey Research Center

By James N. Morgan*

There is a great deal of useful analysis that can be done with available survey data. The quality and quantity of such data are growing, as is the ease of working with it on computers. I want to talk first about some exciting analysis possibilities and data sets; second, a little about the process of locating and getting such data, particularly ours; and finally, about some of the statistical and methodological considerations in analyzing such data.

You might think that the original collectors of the data would already have published the most important findings. Not so. Much remains to be done and I shall mention some main approaches, then some of our more exciting data sets.

Sometimes it is useful to show that *assumptions* which lie behind a theory, or those that are used to test it, are incorrect. Use of self-employment as an indicator of a large transitory component of income is discouraged, for example, when we discover that blue-collar workers have much less stable incomes than the self-employed.

Many theories deal with individuals at the margin, but probability samples contain many people who really have no choices to make. We may need to do some careful selecting of subgroups that can be expected to respond to the particular economic variable of interest. In the labor supply area, for example, it is a fact that "Of all employed male heads of households in 1971 *less than 13 percent* held jobs in which they were free to vary their work hours at well-defined marginal wage rates and nearly half of those gained their flexibility of work hours by taking a second job" (Jonathan Dickinson). Studies of labor supply cannot ignore such constraints.

A logical next step is to search for the optimal disaggregation, that is, for differences in response parameters among subgroups of the population.

Another important kind of analysis deals with the impact of actual or proposed changes on different parts of the population. It is now a common question asked of any proposed changes: "Will it hurt the poor?" We recently pointed out that miles of commuting by car is relatively income elastic, so that a tax on gasoline would *in general* not be regressive. But we could also estimate how many exceptions there were to this rule that might call for special provisions to avoid hardship (Morgan, 1974).

One can develop a better set of assumptions on which to build economic models. To illustrate this: the recent migrants to urban areas, other things considered, earn less than those who were already there when they arrived. Studies of the payoff to migration must clearly be carefully done. Second example: the closer one lives to the center, and the larger the city, the longer it takes, on the average, to get to work. The reason is that not everyone works in the center of town and travel speeds drop dramatically as one gets closer. People who move don't minimize travel plus housing costs. They often move to places farther from where they work and at no savings in housing cost.

What does affect behavior, and why—misinformation, missing information, complex goals, or failure to understand economics? Optimal rules for information search, or lifetime allocation of time and consumption, or optimal inventories are extremely complex, hardly soluble by most of us. Long ago it was discovered that some businessmen kept inventories in amounts proportional to sales even though it was clear to economists that they should be proportional to the square root of sales!

---

* University of Michigan.

Most of the interesting questions of economic behavior are dynamic, yet much survey data is from single cross sections. In spite of this, a great deal of dynamic behavioral analysis is possible even from such surveys. Age cohorts reflect in some crude way life-cycle effects. Some prior information is available from memory. And when there are repeated national probability samples, one can identify subgroups on characteristics that do not change and compare them at different times. Such subgroup differences, which can be expressed as regression coefficients of dummy variables, can be used to separate differences that are effects of different behavior (coefficients) from those resulting from different proportions of the population in the relevant subgroups. Although the third set of components, involving correlations of those pairs of differences, are unavailable without reinterviews, they are likely to be small. There has also been some use of long series of annual or quarterly surveys in time series models directly. For a fuller discussion, see Morgan 1972, Herbert S. Parnes, and Thomas K. Glennan, Jr.

Indeed, one of the advantages of cross-sectional surveys over panel studies is that, being less expensive, they can use larger samples, and with larger samples one has more chance of isolating the marginal subgroups with choices to make or of policy interest.

As more and more data become available from studies which reinterview panels of respondents, data on change can rely less on memory, and the full advantage of the microdata in studying change is available. The models become more complex, and the problem of relating them to aggregate dynamic models arises.

Probably the most exciting and promising possibilities are in the simulation models that use if-then data and iterative computer simulation of the system.

The Survey Research Center has been conducting surveys and making its data available for more than twenty-five years. Let me mention *some* of our available data sets and try to say just a little about some of the possibilities they offer for further analysis.

I. Some Examples of Useful Data Sets

The data available from the Survey Research Center of the Institute for Social Research at the University of Michigan are generally from personal or telephone interviews with small national probability samples varying from 1,200 to 5,000. Such small samples are easy to handle though not ideal for dealing with problems relevant for very small subparts of the population. Sometimes there is oversampling of one end or the other of the income distribution, or of an age group, or of victims of auto accidents or work injuries. The data also contain a useful mix of quantitative economic data, along with attitudes, expectations, knowledge levels, insights, reasons, and demographic facts and background.

First are the annual Surveys of Consumer Finances, 1947–1970, with enough consistency of content, sample design, and methodology to provide trends on many things plus some built-in reinterviews. The data appeared in the *Federal Reserve Bulletins* until 1960, then in annual volumes from the Survey Research Center. There have been smaller surveys, several a year, containing the material on purchase plans, major purchases, and consumer attitudes that were also in the financial surveys.

These two sets of data have already been used in some time series models. There was a four-wave reinterview study of consumer debt use partially imbedded in the last few Surveys of Consumer Finances (see Gary Hendricks and Kenwood Youmans). A series of studies of urban residential choice and the journey to work was summarized in a book by John B. Lansing and Hendricks, and there was a study by Eva Mueller of what machine technology was doing to the worker. A study of early retirement and retirement plans combined a national sample with a sample of *UAW* workers close to retirement age. (See R. E. Barfield and Morgan; and Barfield.) A major study, oversampling lower incomes, of why there were still poor people in 1960 and what they were doing about their children, was followed by another which focused on the paid and unpaid work and related attitudes of families. (See Morgan, M. David, W. Cohen, and H. Brazer; and Morgan, I. Sirageldin, and N. Baerwaldt.) Special studies focused on planned residential environments, the chain of people who moved as a result of new dwellings, on auto accident victims in Michigan, and on the affluent and their work and investment behavior. (See Lansing, Robert Marans, and Robert Zehner; Lansing, C. W. Clifton and Morgan; Alfred Conard et al.; and R. Barlow, Brazer and Morgan.)

The richest, and still growing, data set comes from a national panel study oversampling lower income families, originally funded by the Office of Economic Opportunity and now funded by the Department of Health, Education and Welfare. Two volumes reporting the first five waves are out, a third including the sixth wave is in press, preliminary results from the seventh wave are being tabulated, and plans for the eighth wave are being made. (See Morgan et al., 1974.) Not only does this panel study contain income and work data, and more than usual background material, but for the first five years there were measurements of attitudes and behavior patterns thought to be related to economic change. The fifth-year interview contained a sentence completion test and an attempt to measure achievement motivation. The sample consists of all the individuals in the original sample of families, so those that split off from original families are followed, allowing studies of divorced people, two generations, etc. There is both a family data file and an individual data file, the latter containing data about each individual and about the family he/she was in each year. We have added more than usual environmental data from outside the interview, including county data on unemployment incomes, population growth, and area data on prices. Nonmoney income from assets (imputed rent) and from work are asked about, as well as subsidized food or rent. Hours of work, housework, commuting, illness, and unemployment are measured so that estimates of leisure time are possible. And an extensive set of background information on both husband and wife is available. Repeated measurements of the same set of attitudes and behavior patterns for five years allow studies of changes.

Social scientists in several universities are already analyzing the data and we summarize their work as well as our own in annual volumes of findings. The seven-wave family and individual data tapes will soon be available.

Two studies currently in progress that will probably be available by the end of 1975 should be of great interest. One is a national study of revenue sharing, interviewing administrators and elected officials on the effects of revenue sharing as they see it. The other involves two national samples, one with some oversampling of upper incomes and the other heavily loaded with very high incomes, asking about philanthropic giving of both time and money, related attitudes, and expected responses to further possible changes in the tax laws.

I should mention that this panel of speakers does not cover certain other important data collections or sets of data collections. The Office of Research and Statistics of the Social Security Administration has just issued a *Work Plan* for fiscal years 1975 and 1976 which describes a variety of things, including its continuous work history sample and a ten-year, longitudinal study of retirement, using interviews every two years of the same people. The massive Bureau of Labor Statistics expenditure survey with its five quarterly interviews plus diaries is probably known to most of you.

II. Locating and Getting Survey Data

A long-standing policy of the Institute for Social Research is that as soon as the first publication of findings from any survey is available the basic data are to be available to others for further analysis. The simplest procedure is to read our published reports to find a survey that has the data you want, then get the data and documentation. (See References.) The data library of the Economic Behavior Program (which handles all of the abovementioned studies) tries to work on a no-gain-no-loss basis which in practice has meant a charge of about $350 for the documentation and data from any major survey. For the large Panel Study of Income Dynamics, there are documentation volumes available as an intermediate step in securing the data.

Many studies oversample groups of special interest, such as blacks or low-income families. In order to have unbiased estimates of population parameters it is necessary to weigh each case by the inverse of its sampling fraction. Frequently, the weights supplied also adjust for differential response rates. It is commonly said that with a properly specified model such weights are unnecessary, but in fact our models are almost never properly specified or at least we do not know that they are. For instance, in a sample oversampling blacks, an unweighted estimate of the income elasticity of home ownership that failed to allow for an interaction effect with race (not just a race effect) would produce a weighted average elasticity that is too high since blacks have a higher income elasticity. Analysts usually do not know about all such interaction effects in advance. Many computer programs handle weighted data, and also carry along unweighted numbers for purposes of statistical inference.

Most samples are multistage, stratified, clustered probability samples, not simple random samples, and this produces "design effects"—departures of sampling variances from simple random. Since the losses in information per interview from clustering are usually greater than the gains from stratification, statistical inferences that ignore the design effect will exaggerate levels of significance and underestimate sampling variances. Most studies provide some indication of the average level of design effects. Efficiency losses per case tend to be smaller for more complex statistics like regression coefficients than for means. For a fuller treatment of survey methods and analysis you might want to read our survey methods book (Lansing and Morgan).

III. Some Statistical and Methodological Considerations

Economists trained in the statistical analysis of time series and the traditional econometrics will find that the shift to survey data changes the nature of the statistical problems. There are many more variables, often only loosely related to the theoretical concepts. There are many more "degrees of freedom" from the large sample sizes, so that we have a problem of choosing from among many possible (probably misspecified) models. To make matters more complicated, there are clearly measurement errors of various sizes in the explanatory variables, raising statistical problems that had all but disappeared from the econometric literature. The comparative assessment of the importance of different explanations (explanatory variables) requires some estimate or guess of their error variances. Recent controversies over the relative importance of genetics, parental background, and quality of education in explaining achievement or income have foundered over this issue. It is escape from the degrees of freedom problem provided by the thousands of cases available that changes things most, however. Almost any effect big enough to matter will be statistically significant, and it is the relative reduction in error variance that matters.

Without attempting a lecture in statistics, let me outline some of the problems and some of the suggested solutions: the dependent variable may be skewed, or have heterogeneous variance, requiring transformation or weighted regression (weighting by the inverse of its estimated variance). It may be dichotomous with problems of heteroscedasticity (if it is near 0, or 1) and of predictions <0 or >1. Some argue for probit or logit estimation and we have a multivariate logit program operating. But with reasonably good models, dummy variable predictors, and substantial sample sizes, we think such methods may be unnecessary. It may be a set of classes, the probabilities adding to 1. We have a computer search program that identifies subgroups that differ in their distributions, and another that treats membership in each subclass as a dichotomous (dummy) variable in a separate regression. Or one can convert the problem to a sequential set of conditional probabilities or use a multiple discriminant function. Finally, one can make use of the interrelationships, à la Arnold Zellner. Where there are dependent dichotomies that do not add but are related, such as use of a set of modern practices, they can be handled by methods proposed by M. Nerlove and S. J. Press. One may have a *set* of dependent *variables*. If they are shares that add to 100 percent, we have a search program that looks for subgroups with different share distributions, for instance of the fractions of income from earnings, transfers, or capital. If they are related dependent variables, there is a search program reported for this problem (see M. W. Gillo and M. W. Shelly). For estimation of one optimal model, the Zellner approach is presumably still appropriate. Canonical correlations seem to me to make too many restrictive assumptions.

The explanatory variables may be nonquantitative or skewed quantities. In either case conversion to a set of dichotomous (dummy) variables is usually simplest. (See F. M. Andrews, Morgan, J. A. Sonquist, and Laura Klem; and for a general search program to locate the best linear model, see Sonquist, E. L. Baker and Morgan.) They may be measured with varying errors, and although instrumental variables procedures are often suggested, appropriate ones are hard to find. One can think of the same problem as one of "unobservable variables" or variables only loosely related to the theoretical constructs. In overdetermined systems, these variables can be estimated along with some needed error variances by methods suggested by Goldberger and Jöreskog and available in a program called *LISREL*. (See especially chs. 1, 4, and 5 of Arthur S. Goldberger and Otis D. Duncan.)

There may be interaction effects, the impact of one factor depending on the level of another. Since there are so many possibilities, and they may not be appropriately handled with simple cross-product terms, our *AID-III* search program is often useful to narrow down the candidates. There may be causal paths among the predictors, as when race affects education which affects occupation which affects income. If they all go in one direction, the resulting recursive model is relatively easy to deal with, provided one does not have problems of scaling or interaction effects.

When there are reinterview data from a panel study, one can think of it as a set of related regressions or as a problem of studying individual change. And if there are more than two observations, one may want to treat each pair of periods as a set of change observations or take a longer period of change to reduce the number of potential changers who did not reveal it. Measuring change independently of level is of course necessary because of scale effects, real regression to the mean, and spurious regression from errors in measurement, so we use the average level or a lagged dependent variable among the predictors.

Finally, when there are many categorical classifications, including the dependent "variable" if any, then Leo Goodman (1972 and 1973) has developed a chi-square analogue to the usual variance approach, allowing one to apply all possible tests to a complete hierarchical multiway cross classification.

The most important problem in all this array of statistical approaches, however, is that many of them are designed for, and others are used for, ransacking data in a search for one or a few candidate models, yet we often want some unbiased assessment of the significance, explanatory power, and expected effect of each explanatory variable. That requires preserving an independent subsample not used in the search process. *We now issue our data with four independent subsamples indicated.* (With complex samples, a random subsample is not independent because of the clustering, so only the sampler can designate independent part-samples.) How much is kept for the assessment depends on the relative importance of selecting a model versus estimating its parameters and its power.

IV. Conclusion

I hope all this discussion of methods will not discourage anyone from getting some of our data and working with them. A great deal can be learned with relatively simple methods, and most of the refinements affect estimated sampling errors far more than they affect estimated relationships.

One reason those of us on this program are eager to see more economists analyzing the available data is that we are concerned about the vast unmet needs for more and better survey data. We frankly hope that if more people start using the existing data, the needs and uses of additional data will be more apparent and the support for their collection more enthusiastic. Three examples: (1) a decade of wealth accumulation, wild changes in returns in different kinds of assets, inflation, and massive shifts of portfolios has gone by without any decent information about what has been motivating people or what they plan to do next with their savings. (2) We talk of urban development, public services, housing policy, and trickle-down, but there are no national studies on what people want, pay for, and get in housing, neighborhood, and community. Without some such bench-mark measurements, assessing who benefits from new construction seems bound to be treacherous. (3) Earlier studies seemed to show a massive trend toward earlier retirement, and the young planning still earlier retirement, but no one has remeasured the plans nor found what the current inflation is doing to them. I could go on, but you can supply your own agenda. The real problem is that behavioral economics, to which we really must turn to tighten our models, must mostly make use of the natural experiments of history. This means collecting data with a calculating look at what has been going on and what we expect to happen next.

Potential Applications of Census Bureau Economic Series in Microdata Analysis

By SHIRLEY KALLEK*

Even today most economic research related to the enterprise or firm is limited to the utilization of aggregated data series. In fact there are few economic models in use today which do not depend upon macro rather than microdata sets. In this context, macrodata are defined as aggregated statistical series and microdata as information about an individual firm. Even though the theory of value is dependent upon decisions made by the individual enterprise, most econometric models deal with macro relationships. The relationships in any macro series are normally complex in nature since highly aggregated series reflect both actions of many different individual units and the shift in distribution of those units.

The basic questions that arise seem to be: Will analysis of microdata sets prove more useful in explaining economic phenomena than aggregated series? Will the integration of microdata sets with macro series enhance economic research and shed more light on existing economic theory? Although the consensus from most available literature indicates that the answer is in the affirmative, relatively little progress has been made in extending the use of microdata analysis. The Census Bureau, probably more than any statistical organization, has the most complete set of information about the characteristics of enterprises and their establishments—data which come from quinquennial census programs, from annual reports, and on a more limited basis from monthly and quarterly surveys. Moreover these data are available over long periods of time. The usefulness of this large body of data could be enhanced greatly through analysis at the micro level, i.e., through studying the behavior of the individual firms which comprise the statistical series. I would like to talk about some of our past efforts in exploiting this information base, why they were not satisfactory, and what our current plans are in this area.

In general, at the Census Bureau the use of microdata as a tool for fundamental research about the enterprise or economic reporting unit has lagged behind the progress made in the demographic area. The primary reason I believe for not tapping the vast store of microdata available in the economic sector has been its general unavailability to most researchers because of confidentiality restrictions. Reports filed by business concerns are strictly confidential by law and can be used only by employees of the Census Bureau for statistical purposes. We have not yet found any satisfactory means of issuing a public-use tape of individual establishments or firms which would eliminate the identifying factors of the individual firm and still permit the information to be useful. The highly skewed distribution of business establishments is not similar to the data in the demographic areas. Also utilizing a time series file of establishment reports presents new problems in terms of more subtle disclosure possibilities than the Bureau has ordinarily had to face in publishing data for single time periods.

---

* Associate Director for Economic Fields, U.S. Bureau of the Census. I would like to thank Thomas Mesenbourg and William Menth of the Census Bureau staff for providing assistance in the preparation of the special tabulation.

This, in effect, means that any research effort would have to be performed here at the Census Bureau or under contract by Census Bureau employees, and that the resulting analysis would be released only after it had been reviewed for possible disclosure. We have used both methods in the past for the small number of microdata studies we were involved in. Some possible alternatives will be discussed later in this paper.

Even if the problems associated with disclosure were resolved, there would remain other significant cost and data problems. Most researchers attempting to use microdata files have had frustrating experiences. This is still an area where much more knowledge must be obtained before this type of analysis can be optimized. The cost and complexity of handling these massive data files are enormous for any one individual or even for most groups. Then there are the numerous problems associated with utilizing existing microdata sets which are obtained as a byproduct of survey collection. Many of the issues and problems associated with the utilization of existing microdata sets for economic research have been discussed by F. T. Juster, G. H. Orcutt, and H. W. Watts, as well as Nancy and Richard Ruggles. It is worthwhile to discuss some of these problems since they are typical of the difficulties encountered when attempting to use any set of data tapes for purposes other than were originally intended. If they can be solved, significant progress can be achieved.

The Census Bureau has, naturally, placed its emphasis on the collection of data for the compilation and publication of statistical surveys and truthfully has not given much attention to the use of these data as inputs for microdata analysis. Thus the entire systems design, review, and processing phases for any survey are generally not compatible with the analytical needs. For example, in most surveys designed by the Bureau, the data base file covers only the two periods, current and previous, which are needed for the review and publication of the series. The volatility of the economic reporting units (from mergers, closings, etc.) results in numerous changes in the identification numbers of the reporting units. For purposes of the survey review, comparability of the reporting units and a common identification number need be maintained only for the two periods; for economic research purposes, this comparability must be extended over the period of the entire file.

Questions also arise as to the comparability of reporting units. Should changes reflected in the reporting unit as the result of industry code changes, ownership changes, etc. result in treating the reporting unit as a discrete entity in each survey year, or should such results be linked? If they are linked, the disclosure problem is increased enormously. In some instances sampling rules for surveys will treat a change in ownership as a "death" and in others as a "merger" of the acquiring firm. Thus there may be inconsistencies from survey to survey depending upon the sample design and requirements of the survey. Moreover the changing identification number due to mergers, changes in corporate structure, etc. results in difficulties in matching records from one time period to another.

There are also omissions or data errors in the records of individual establishments. Some have not been detected and never will be. The review of data for publication totals can be quite different from that which is needed for manipulation of the information at the micro level. Our review process does not "clean" the data beyond the point needed for tabulation analysis. It is the hope of every statistical agency that any remaining errors are minor. More important are the errors which are detected during the survey processing, but which, primarily because of budgetary reasons, are not carried back to the computer tapes although the corrections are reflected in the published data.

Many Census Bureau surveys are based on sample panels which are updated at periodic intervals. A continuous time series for a long period of time will therefore of necessity be limited to the larger establishments. The practice of completely changing the noncertainty portion of the sample to minimize reporting burden aggravates the problem of comparability for the researcher. These are just some of the examples which can affect any examination of the microdata. If research utilizing these data is to be encouraged, accommodation to these conditions must be made in the design of the operating system.

In the early 1960's, the Bureau attempted a major longitudinal study of economic establishments, but the results were less than encouraging, primarily due to inexperience in resolving the problems just discussed. Several years of work went into creating a file of statistical histories for individual manufacturing plants, primarily using data reported in the Annual Survey of Manufactures.

Even though these basic files were difficult to use and were deficient in many ways, several studies utilizing these data were undertaken. One was the Ruggles project, "The Behavior and the Characteristics of Manufacturing Establishments in the U.S. 1954–1959," undertaken under the joint sponsorship of the Social Science Research Council and the Bureau of the Census, which related to the price-cost behavior and characteristics of manufacturing establishments. Another outgrowth of the establishment time-series project was a pilot study on measuring capacity through the peak performance potential approach. In addition, the Bureau of Labor Statistics conducted a methodological study to explore whether plants with high productivity levels could serve as a guide to projecting future productivity increases of an industry.

The major lesson learned from the 1960's time-series effort is that it is almost impossible to reconstruct an historical file of individual establishment records. The tracing of identification numbers for individual establishments and the *ex post facto* correction of data fields pose processing problems which are almost impossible to overcome.

If the Bureau is to provide the ability for microdata analysis, the concept must be built into its operating system, and research efforts must be undertaken here at the Bureau which will permit optimum manipulation of the data. Alternatives to the issuance of public-use tapes must also be explored, since our research over the past twenty years has not resulted in any significant progress in resolving the disclosure problem. We have established an economic research unit whose responsibility will be to prepare microdata analysis for others on a reimbursable basis. This hopefully will resolve some of the operational problems of the past where we tried to have these studies prepared by the same operating staff responsible for the survey management.

This unit, under Bureau sponsorship, has undertaken a research effort which will attempt to match information from our demographic files with our economic files. In particular, the Bureau has at its disposal information about individual workers. We are attempting to see if it is possible to match the individual characteristics of employees with the operating characteristics of the establishments in which they are employed, interrelating such variables as age, race, and income of employee with size of the firm, its industrial classification, its geographic area, capitalization, etc. Work is just beginning in this area and the success of the project is still not known. If fruitful, it can open up an entire new area which has never been tapped.

We also plan to explore the development of a wide range of variance-covariance matrixes which could be made available to outside researchers. Initial review has indicated that by using a sufficiently large number of observations and by withholding some of the constants it may be possible to release such matrixes without problems of disclosure.

Another new approach, in effect, will integrate the needs of microdata analysis into the data system. We think that this is now possible with the introduction of an industrial directory system here at the Bureau. The Industrial Directory which has been under development for the past several years is now becoming operational. The Directory, which is confined to Bureau use, is basically a computerized file of all companies and their constituent establishments. Fundamental to this system is the inclusion of all changes in ownership, linkage of identification numbers, changes in industry classification, etc. for all multi-establishment firms and for all firms reporting in the Bureau's current surveys. This file, while too large an entity to manipulate, will be the basis for maintaining the Master Sample. The Master Sample was designed originally to control the quality of the internal processing of the 1972 Economic Censuses program files and to identify reporting units which could be subjected to intensive quality checks both before and after the full-scale processing. While the main purpose was to prevent systematic errors in processing, the Master Sample is large enough to measure the various attributes of the universe with adequate reliability. The Master Sample can be a powerful tool for the analysis of economic microdata at reasonable cost.

The sample itself contains about 200,000 employer establishment records and includes all economic divisions. It basically provides for a 2 percent sample of all establishments with less than 250 employees and a certainty stratum of all employer records with 250 or more employees. For example, approximately 30,000 manufacturing plants, 10,000 wholesale establishments, and about 50,000 retail stores will be identified. It started with the 1972 report year and will be maintained on an annual basis. The noncertainty segment may not, however, be large enough for the manufacturing sector and a subsample from the Annual Survey of Manufactures panel may have to be included in the Master Sample. As a tool for analyzing economic microdata, the Master Sample lends itself to tracing individual cases over time at nominal costs. Changes in industrial activity, growth patterns, and geographic mobility can be followed by matching manageable record files from year to year and census to census. Moreover, correction of the data in the basic computer files is being built into our regular processing system.

In view of the considerable interest in this area, the Bureau is again giving considerable attention to ways of releasing new types of analytically useful data that can be derived from examining the interrelationships among the different variables of microdata sets. One of the possibilities is the publication by the Bureau of various analytical ratios and studies which would permit a deeper examination of the underlying data. There are many advantages to be gained in examining more detailed sets of the same group of aggregated data. First, underlying movements of economic phenomena may be masked by aggregative totals. Movements of larger plants can react quite differently from small ones. In fact, in many cases that is exactly what we want to find out. To show the value of such disaggregation, the establishments in the data files for the 1970–71 Annual Surveys of Manufactures were matched and analyzed to attempt to determine if there is a

TABLE 1—QUINTILE DISTRIBUTION OF ESTABLISHMENTS BY RATE OF CHANGE IN PRODUCTIVITY (1970–71) AND EMPLOYEE SIZE FOR MANUFACTURING PLANTS

Quintile	Mean Rate of Productivity Change (1970–71)	Percentage of Establishments in Quintile (By Employee Size Class of Plant)		
		1–49 Employees	50–249 Employees	250 or More Employees
1	.96	25.4	19.7	16.8
2	1.05	19.9	21.4	20.9
3	1.09	19.7	19.7	23.1
4	1.12	16.1	20.7	22.3
5	1.21	18.9	18.5	16.9
Total	1.08	100.0	100.0	100.0

Source: Unpublished tabulations from 1970–71 Annual Survey of Manufactures, U.S. Bureau of the Census.

direct relationship between the size of an establishment and its rate of change in productivity. For example, the dollar volume of adjusted value added (*AVA*) was used as the measure of output and the productivity for each establishment was computed by dividing *AVA* by the total manhours worked for both years and the rate of change from 1970 to 1971 was derived.

In interpreting the rates of change a word of caution must be given. The productivity measures used in this example are rather crude and are based on dollar volume of output, rather than physical output. Unlike physical output, value of output is affected not only by difference in input costs, but also by differential demand factors for different industries and for different establishments within the same industry. In addition, total manhours worked are affected by capital input.

The establishments within each of the 420 manufacturing industries were ranked by rate of change in *AVA* per manhour, placed in approximated quintiles in ascending order according to their rate of change from 1970 to 1971, and sorted by three employee size classes. While the overall mean rate of change was 1.08, the mean rate of change varied from .96 for the first quintile to 1.20 for the fifth quintile.

As seen in Table 1, there are significantly different patterns for each of the three size groups. The largest employee size category appears to be almost an inverted U-shaped distribution; a larger number than would be expected fall in the second, third, and fourth quintiles. For the smallest size category, it is evident that a relatively higher number of establishments fall into the first quintile. For the middle range, i.e., 50–249 employee size category, the differences among quintiles are less pronounced. It appears that the larger establishments are much more stable and are less likely to experience extreme increases or decreases in rates of productivity change. The smaller establishments, i.e., under 50 employees, are much more likely to experience very small or even declining rates of productivity. Further investigation would be necessary to see what factors influence these changes.

It would be interesting to correlate the rates of change with gross assets or changes in gross assets of the establishment to examine productivity and investment behavior. Or, if data for additional years were linked to the 1970–71 file, would establishments increasing in size have different productivity rates compared to those that remain fairly stable in size?

Needless to say, this is just a fairly simple example of the types of research which can be undertaken when using microdata. Once the basic file is extended to include a longer time period, the possibilities for research at this detailed level can become even more meaningful. Hypotheses can be tested more fully and changes over time can be examined for any number of variables, and the behavior of individual establishments at different phases of the business cycle can be studied. The possibilities are almost limitless for there is a body of data waiting to be analyzed.

The Experimental Panel Data Resources at the Poverty Institute Data Center

By KATHERINE DICKINSON AND HAROLD W. WATTS*

The Institute for Research on Poverty has been involved in two negative income tax experiments sponsored by the Office of Economic Opportunity: The New Jersey Income Maintenance Experiment in New Jersey and Pennsylvania (conducted jointly with Mathematica, Inc.); and the Rural Income Maintenance Experiment in North Carolina and Iowa. The information collected in these experiments form two very large panel data bases. The Data Center was established with support from the office of Health, Education and Welfare to facilitate and encourage research on these data by providing consultation, documentation, and data files to potential users. The Data Center is also planning to provide a combined data base by merging the comparable questions used in both the urban and rural experiments.

The Data Center was created in the belief that full scientific and social benefits from the large expenditure of effort and resources which the experiments represent can only be realized from extensive and critical analysis from many points of view. While there is no way of assuring that this will happen, there are substantial obstacles in the way of using large and complex data files that can be removed. In addition it is possible to use every available opportunity to encourage, inspire, or provoke research scholars to engage in the challenging task of exploiting a new and, in part, unique body of evidence. In this presentation we aim at creating an interest in using the experimental data, and indicating how the Data Center can ease the always difficult job of getting on working terms with a new data file.

I. The Experiments Briefly Described

The New Jersey Income Maintenance Experiment was the first large-scale social experiment conducted in this country. It was a carefully controlled field test on the effects of eight negative income tax plans. Such a plan can be defined by the guarantee level (the level of payment the family receives if it has no other income) and the tax rate (the rate at which payments are reduced for each dollar of other income). Various combinations of four guarantee levels and three tax rates were tested. Table 1A shows the number of families on each plan for the urban experiment. Experimental families received biweekly checks reflecting their plan and their three-month average income; control families received nominal amounts for participating in the interviews.

The sample included 1,357 families who lived in one of four Northeast metropolitan areas (Trenton, Jersey City, the Paterson-Passaic *SMSA* in New Jersey, and Scranton, Pennsylvania). Each family initially contained an able-bodied man aged 18 to 58 (in most cases the head of the household) and had income of less than 150 percent of the official poverty line. This experiment concentrated on the effects on men, since few other transfer programs extended eligibility to them and thus little was known about their work-effort response to transfers. The experiment lasted

[a] This number differs from the actual sample size of 1,357 because of sampling shortfall.

three years in each site, starting in the summer of 1968 in Trenton and ending in the fall of 1972 in Scranton.

The rural experiment was a similarly designed study which involved 809 families living in the rural South and Midwest (Duplin county in North Carolina and Pocahontas and Calhoun counties in Iowa.) There were 217 farm families included in the sample. This experiment studied eight plans, six of which were also used in the urban experiment. The allocation of families to various plans is shown in Table 1B.

The majority of the rural sample consisted of families with male heads between 18 and 58, but there were 108 nonaged female-headed families and 114 families with heads over 58. The income cutoff for the rural experiment was also 150 percent of the poverty level. The experiment was conducted from early 1970 to mid-1973.

This necessarily abbreviated description of the experiments can be extended by any or all of the items listed at the end of this

TABLE 1B—ALLOCATION OF FAMILIES TO EXPERIMENTAL PLANS IN THE RURAL INCOME MAINTENANCE EXPERIMENT

paper. References dated 1973 or later include experimental findings as well as some descriptive accounts. The Users Manuals for the Data Files, described below, also contain complete descriptions of the experimental design and procedures.

II. Nature of the Data Collected

The families in both experiments were given a baseline interview, twelve quarterly interviews during the operation of the experiment, and a follow-up interview three months after the last payment was made. Approximately 3,000 variables were measured, and the information collected covers many aspects of behavior, attitude, and circumstance.

The primary goal of the experiments was to measure the work-effort response to both an increase in income and a decrease in the marginal wage rate. To monitor changes in labor supplied, each quarterly interview contained a core set of questions on earnings, hours of work, and other labor force behavior (see Table 2). These core questions were asked of up to five adults in each family in the urban experiment and of all adults in the rural families. The questions common to both studies for all quarters concern the previous week's hours, earnings, and occupation. The rural study also concentrated on farm income and expenses each quarter.

The noncore section of the interviews contained questions on economic, social, and psychological aspects of the families' lives which either could be changed by the experiment or could influence the effect of a negative income tax. These questions were rotated among the quarters and were generally asked two or three times. Tables 3 and 4 contain lists of the major categories of the information obtained.

Three general characteristics of the data deserve special mention here. First of all, they are panel data using the household-family as the primary observational unit, but allowing substantially complete derived panels of individuals to be assembled as well. As with any panel data file, there

TABLE 2—CORE VARIABLES COLLECTED EVERY QUARTER IN THE EXPERIMENTS

New Jersey Experiment	Rural Experiment
Family composition	Same
Labor-force experience last week Hours—main job, overtime, second job, hours lost Earnings Occupation and industry	Same
Labor-force experience last month	Labor-force experience last thirteen weeks
Sources of unearned income	Same
Housing costs	Same
—	Migration
—	Farm and business income and expenses
—	Unpaid hours in farm or business for women
Travel to work	—
Child care and support	—

Table 3—Other Categories of Data Collected on the New Jersey Income Maintenance Experiment

Attitudes
—anomie, control of future, happiness, ladder of life, worry, self-esteem, social desirability bias, time horizon, future events, political liberalism, awareness, and integration

Education and Ability
—educational attainment of children and parent's aspirations, education of head and wife, education of parents and siblings, Ammons Quick Test for head

Family Information
—composition, social and demographic characteristics, marital history, religious background, family integration, homework and children's chores, child care, child support, family planning

Financial Information
—expenditure patterns of food and clothing, installment buying, debit, savings, durable goods, and insurance

Housing and Property Ownership
—housing status and costs, housing conditions, home improvements

Job History
—lifetime job history of head, job history of wife since current marriage, occupational experience of parents and siblings

Job Satisfaction
—attitudes toward job mobility, job expectation, job satisfaction and alienation

Job Training Programs
—participation of head and wife

Leisure Activities
—time-use study, family activities, sports, hobbies and vacations

Media Use

Medical and Dental Experience
—attitudes, psychosomatic scale, current care, long-term disabilities, hospitalization, dental care

Group Involvement
—organizational membership, social integration, neighborhood ethnicity

Residential Mobility

Welfare Experience
—history and during experiment

Table 4—Other Categories of Data Collected on the Rural Income Maintenance Experiment

Attitudes
—life satisfaction, self-esteem, self-comparison, ladder of life, personal efficacy, future orientation, family loyalty, anomie, social desirability bias, time preference

Political
—efficacy of and attitudes toward central government, political behavior

Education and Ability
—expectations for children, educational history, children's performance, Ammons Quick Test

Family Information
—family planning, family relations, division of labor, marital history, social and demographic characteristics, child care

Annual Finances
—income, net worth, investments

Farm
—government programs, crops, yields, tenure, livestock

Other Financial Information
—credit and debt, insurance, consumer goods expenditures

Food and Nutrition
—24-hour intake recall, food expenditures and budgets, food preparation, food subsidies, attitudes about food and cooking, food during pregnancy

Housing
—quality, costs, and home repairs

Job History and Attitudes
—job history, attitudes toward job mobility, job satisfaction, attitude toward working wives, work-related and job-search expenses, frequency of pay, fringe benefits, travel to work, work orientation, children's jobs, desired work hours, discrimination

Health
—use of health facilities, current state of health

Activities
—social integration, organizational involvement, leisure activities and vacations, religious activities

Public Programs
—attitudes, knowledge, and use of welfare, social services and agricultural programs

Teenage Supplement
—attitudes toward school, aspirations for school and job, social and family integration, self-esteem, psychosomatic scale, delinquency

are problems with interrupted and incomplete data series for some persons or households. But there is also the opportunity for longitudinal analysis based on intertemporal variation which can, as in any panel data, be compared with the interunit variation of the cross section.

A second and unique feature of the data lies in the frequency of interviewing. Almost all currently available panel surveys are annual or less frequent. The experimental panels were interviewed quarterly and consequently the data can be used for examining dynamic adjustment processes which require more closely spaced measurements.

Finally, the panel data records the behavior of a sample which was exogenously "treated" with various "doses" of income subsidy on a controlled and randomized basis. This is, of course, the principal unique feature of this data resource. This feature affords the possibility of examining the consequences of experimental variation and to contrast them with the effects of natural or spontaneous variation observed (across individuals or over time) in nonexperimental panels or in the control group. It is hoped that, as for experimentation in the physical sciences, the introduction of clearly exogenous variation will simplify the identification of causal relations.

III. Uses of the Data

The estimation of the labor supply response to the guarantee levels and tax rates was the major focus of the experimental design and of the initial analytic reports. These studies provide evidence on the work-effort effects for wage earners, the self-employed, wives and female heads, and other family members. Information was also collected that makes possible the study of experimental effects on wage rate. A variety of such effects might be expected. If a worker does reduce his hours of work, it may result from not working overtime or on a second job, both of which usually have a wage rate different from the main job. Information on these work hours is available every quarter. Having a floor on income also reduces the risks involved in changing jobs. Extensive job histories, both before and during the experiment, were collected for the head and wife and can be used to test this hypothesis. A guaranteed income would also make job training more attractive. Prior education and participation in training programs during the experiment were asked of the head and wife.

The farm families might be expected to engage in more risky enterprises as a result of the experiment or increase specialization in one product. The guarantee might also provide a floor on farm investments in such things as fertilizer which have a very high payoff.

If families do reduce the number of hours worked in the market, it is important to determine what the family does with the increased time. The parents may, for example, devote more time to their children, resulting in a more integrated family and in the children doing better in school. Both experiments contain measures of time-use, family integration, and children's educational attainment; the rural data even contain information gathered from the schools on the children's performance.

Unlike food stamps or housing allowances, a negative income tax places no constraints on how income is spent. An important aspect of these studies is to determine how the payments were used and specifically whether these transfer plans achieved the goals of the in-kind transfer programs. Data on housing, food, and clothing expenditures were collected as well as purchases of furniture, appliances, and vehicles. These durable goods expenditures and the data on savings and debt can also provide insights into the validity of the permanent income hypothesis and evidence on the short-term nature of the experiment.

Health can affect the labor supply response and can itself be changed by the experiment. The latter response would be expected to include a substitution effect as well as an income effect, since time is an important cost of health care. A substantial amount of health care and disability information was collected on the husband, wife, and children, particularly in the urban experiment.

Social psychological attitudes also may interact with labor force behavior and be themselves changed through a negative income tax. It may be that only families poorly integrated into the major values of society would reduce work effort. Further, the increased income and reduced stress resulting from a guaranteed income might increase self-esteem, feelings of personal efficacy, and the quality of life of the recipients. The result might also be more integration into society. These hypotheses, similar to some used in the Survey Research Center's Panel Study of Income Dynamics, are testable with these data.

Other aspects of social behavior which could respond to the experiment involve the composition of the family itself. Increased stability might be expected because coverage is extended to intact families under these plans, in contrast to current transfer systems for which male-headed families are often ineligible. Further increased income and less variability might produce less family stress. Family planning decisions could be affected not only from increased income but also because benefits are tied to family size and because the cost of time inputs to children is reduced.

Many of the above hypotheses have been given a first examination in the final reports for these experiments and in other research. The bibliography below provides references to available materials and the Data Center endeavors to provide references to work completed or in progress on various subjects for those interested in pursuing a topic.

IV. Obtaining the Data

In general, the complete data sets from the experiments are not available. They are simply too large and too complex to be distributed on a routine basis. Instead, the Data Center can provide a tailor-made subset of the data, according to the user's specifications. For the urban experiment, the data tape used in most of the economic analysis for the final report is also available. The project to merge the two data bases is still in the planning stages but information should be available by mid-1975.

The Data Center has compiled User Manuals which document the experiments (including study design, sample selection, the rules of operation, and methodological issues) and the data (detailed descriptions of the variables collected and instructions for specifying extracts). These manuals can be obtained from the Data Center upon request. After consulting the manual the user can then order (without charge) code books for all the possibly relevant categories of data, which contain the actual questions asked, the quarters each is available, and the coding sets used. From these the desired variables can be specified. Charges for extracts are at marginal cost and generally are less than $300.

The address of the Data Center is as follows:

Data Center
Institute for Research on Poverty
University of Wisconsin
1180 Observatory Drive
Madison, Wisconsin 53706

General or specific inquiries are cordially invited and suggestions as to how we can be of greater assistance to research analysts are always welcome.

THE BEHAVIOR OF FIRMS IN OLIGOPOLISTIC MARKETS: IN THEORY AND PRACTICE

Firm Decision-making Processes and Oligopoly Theory

By PAUL L. JOSKOW*

The typical industrial organization economist interested in examining the behavior of firms in market environments characterized by small numbers does not approach his task with any unified set of analytical tools which one could call the theory of oligopoly. Instead, he comes armed with a whole smorgasbord of formal models, *ad hoc* models, case-study information, stories, and vague notions concerning the impact of business psychology and sociology. The various theories, whether they be formal or informal, are based on a bewildering collection of a priori behavioral assumptions, formal mathematics, hard case-study information, casual empiricism, hand waving, and as much as possible of the traditional theory of the atomistic competitive firm.

For those of us interested in public policy analysis this state of affairs is troublesome. On the one hand, many of the interesting policy issues arise in markets dominated by a small number of large firms and therefore some viable alternative to the competitive model is desirable. On the other hand, existing formal models often do not provide a useful framework for policy analysis.

This essay proceeds by briefly reviewing the formal models which appear to make up the corpus of formal oligopoly theory. These models are then evaluated in terms of their ability to generate testable hypotheses that can differentiate one model from the next and oligopoly behavior from competitive market behavior, as well as the usefulness of these models in the analysis of particular markets and particular public policies. I conclude that there is little qualitative difference in the implications associated with most of the models, but, more importantly, that the formal models are not really utilized by serious students of actual markets and public policies. Rather, the important characteristic of much of this applied work is the use of informal models, "stories," the consideration of particular decision-making processes, situation-specific considerations of uncertainty, information costs, other transactions costs, and various institutional constraints. Since it appears that the important characteristics of oligopoly behavior are not captured by conventional models, some suggestions for further research which deals more explicitly with the behavior associated with the "oral tradition" of industrial organization are given; specifically, more careful analysis of actual firm decision-making processes and the phenomena which determine them is called for.

I. Formal Models

The formal modeling of duopoly and oligopoly has a long tradition. Virtually all of the modeling efforts (a) assume that firms seek to maximize profits and (b) make some behavioral assumption concerning the ways in which a particular firm relates to the others (actually or potentially) in the market. What makes oligopoly theory different from competitive market theory is the recognition by firms that outcomes of their decisions are affected by the behavior of other firms. However, the picture of the firm painted in most formal oligopoly models is really not much richer than that of the "black box" competitive firm. The major difference is the replacement of the obscure Walrasian auctioneer of competitive market models with specific price adjustment rules for individual firms. Exactly how different the resulting market behavior is depends upon the particular interrelationships that are assumed to characterize the environment in which a particular firm attempts to maximize profits.

---

* Massachusetts Institute of Technology.

Within the formal modeling tradition two basic trusts have emerged. While both make the assumption that firms attempt to maximize profits, they are characterized by different types of behavioral assumptions. The first set of models is characterized by behavioral assumptions concerning the ways in which one firm perceives or responds to the actions of others already existing in the market (W. Fellner). The typical model specifies a set of behavioral assumptions, derives the profit-maximizing conditions given these assumptions, and examines the nature of the resulting equilibrium in a market with two or more firms. The work of Augustin Cournot, J. Bertrand, F. Y. Edgeworth, and H. von Stackelberg exemplifies this tradition of formal modeling. The kinky demand curve model attributed to Robert Hall and Charles Hitch and to Paul Sweezy is often regarded as an approach in itself; however, the basic methodology is very much in the same tradition as the others.

The second formal modeling approach essentially ignores the interdependence of firms in existence and concentrates instead on the behavior of a firm faced with potential entrants into the industry. Such models either treat the existing market structure as pure monopoly or assume implicitly that existing firms have been able to collude and can coordinate their pricing or output behavior. These "limit-pricing" models make assumptions about the ways in which potential entrants perceive the response to entry by existing firms (they might be assumed to maintain their output but lower their prices in the face of entry) and determinants of the rate of entry, and recognize explicitly that entry is neither generally completely blockaded nor completely "easy." In the most simple models, the existing firm chooses some limit price, generally above the competitive price, but below the short-run profit-maximizing price, at which potential entrants would find it unattractive to enter the industry. The work of Roy Harrod, H. R. Edwards, Joe Bain, Paolo Sylos-Labini, F. Modigliani, and J. Bhagwati is characteristic of this literature.

Recent extensions of the limit-pricing idea have introduced concepts of entry uncertainty, the recognition that entry takes time and will occur at different rates depending on expected profits, and the opportunity to choose a trajectory of prices over time rather than a particular preentry limit price. The works of D. Gaskins, M. Kamien and N. Schwartz, and D. Baron are examples of recent extensions of limit-pricing notions recognizing uncertainty and dynamics more explicitly. While there have been a few attempts to bridge the gap between the two thrusts of formal oligopoly modeling (F. Fisher and C. Frank, Jr.), extensive efforts in this direction have not been made.

A natural question to ask is what empirically testable hypotheses can be derived from these models. In particular, can they lead to hypotheses that can be differentiated from behavior implied by models of perfect competition, and can they be differentiated one from the other?

Virtually all of the models which attempt to recognize the interdependence of firms existing in the market lead to the conclusion that prices will lie somewhere between the competitive price and the short-run monopoly price in equilibrium, and that as the number of firms in the market increases, the equilibrium oligopoly price will approach the competitive price. The kinky demand curve model implies that prices in oligopolistic markets will be insensitive to moderate swings in the costs of production. While many problems exist with the kinky demand curve model as formulated (F. Scherer and G. Stigler) and while a number of researchers have purportedly disproven the validity of the empirical implications (Stigler, W. Simon, and W. Primeaux Jr. and M. Bomball), both the essence of the model and its empirical implications continue to be taken seriously by many economists. Given a continued belief in the "stylized fact" associating price rigidity with concentration, supporting empirical work (Stigler and J. Kindahl, p. 91), *and* general dissatisfaction with the kinky demand model itself, combined with the inability of the other traditional models to generate this empirical result, we must wonder why more effort hasn't been directed toward constructing a more satisfactory model. Except for the kinky demand curve model, however, the interdependence models are not particularly rich in empirical conclusions especially with regard to short-run dynamics and the characteristics of the path toward a new equilibrium.

The limit-pricing models suggest that the limit price will lie somewhere between the short-run monopoly price and the competitive price. The difference between the long-run equilibrium limit price and the competitive price varies directly with the scale at which minimum average cost is achieved, other barriers to entry, the discount rate, and the rate of growth of demand (Gaskins). It varies inversely with the elasticity of demand, the extent of the market, the probability and rate of entry (*ceteris paribus*), and the level of risk aversion. As a result we would expect to observe higher profits in markets with substantial scale economies and technological change, entry of new firms over time (as long as there is uncertainty about entry and entry is not instantaneous or "all or nothing") and a declining (or perhaps eventually constant) market share for the dominant firm.

All of these predictions are consistent with available empirical evidence. There seems to be a positive relationship between concentration and profitability (Bain, Michael Mann, R. Sherman and R. Tollison), as well as a positive relationship between profitability and barriers to entry (Bain and Mann). There is entry over time into many markets which historically had one large dominant firm (steel and tin cans are standard examples, but aluminum and shoe machinery are counterexamples) and the share of dominant firms has often tended to decline at least during some part of the history of the industry (some examples and counterexamples). In addition, we do observe price leadership and intermittent warfare in some industrial markets (the cigarette market is an example).

The limit-pricing models have been advertised as a great step forward, but the vast array of general empirical results that we have makes it extremely difficult to differentiate among these models as well as between limit-pricing models and interdependence models. Firms could be the most naive, obeying the Cournot assumptions and ignoring potential entrants, and we would still observe entry, declining profits and prices, and declining market shares over time. Whether the existing firms are rational limit pricers or not, excess profits will eventually attract entry, and the degree of entry will depend on how easy it is to enter. I suspect that most of the *qualitative* results of the limit-pricing theories would go through with a simple Cournot model plus entry. As far as I am concerned the limit-pricing models are more an addendum to the theory of monopoly, recognizing the possibility of entry and the optimality of long-run rather than short-run profit maximization, than a major insight into the economics of behavior in oligopolistic markets.

II. Formal Models and Empirical Analysis

In a sense the ultimate test of the utility of the various models is whether they prove useful to people involved in analyzing problems involving actual markets or groups of markets. I suggest that not only aren't they particularly useful but also that they really aren't even used.

Let's first consider empirical work that has been done to assess general relationships between market structure and behavior. Virtually none of it appeals to particular formal models of oligopoly markets. It recognizes that prices and profits should be positively correlated with such things as concentration, barriers to entry, product heterogeneity, etc., but the empirical specifications appeal more to a commonsense understanding of the way markets work in general rather than to particular models. Variables reflecting the behavioral assumptions specified in some models and found in certain markets, such as price leadership and price rigidity, are rarely used as explanatory variables. The oligopoly models have little or nothing to say about important issues, such as research and development efforts, technological change, wage and price adjustment rates, and technical efficiency, and how such behavior might differ between and among industries with competitive and oligopolistic market structures.

When we move from general empirical work designed to elucidate basic propositions about the relationship between structure and behavior to studies of particular markets, any facade that the investigation is based on some formal oligopoly theory or set of theories is dropped altogether. Serious investigators get right down and attempt to understand the actual interactions among firms, the ways in which decisions on prices, outputs, research and development activity, and entry are made, and the major decision variables used to signal to, coordinate with, and punish rivals who don't fall into line for the particular industries under study (C. Kaysen, J. Dirlam and A. Kahn, A. Chandler, R. Nelson (1962), and many others). Plausible and interesting stories about pricing, output, entry, and research and development decisions abound as a result of these studies.

Somehow one gets the distinct feeling that the important messages are being carried by the informal theories, stories, and behavioral observations, and that the formal models are trotted out *ex post* to demonstrate that some kind of formal apparatus can explain or incorporate some of what is actually being observed. The formal models often have great mathematical elegance and are fun to play with and teach, but at least from this author's vantage point their existence has had a negligible effect on applied research and policy analysis in the industrial organization area. General policy prescriptions and uncertainties regarding concentration, price rigidities, barriers to entry, market definition, tacit coordination, etc., seem to exist independently of the formal modeling tradition.

III. A Behavioral Approach

The major problem with the conventional models of oligopoly arises from an approach which takes as given the neoclassical black box profit-maximizing firm embedded in a competitive market and then tacks on simple behavioral rules to turn it into an oligopoly model. The interesting stories which characterize much of the research on particular markets and responses to particular policy changes seem to speak much more to the ways in which actual firms make actual decisions. This oral tradition of industrial organization digs into the actual organizational structure of firms, decision-making processes within firms, information flows, environmental perceptions, business psychology, and institutional constraints and recognizes that these considerations are what is important. Formal oligopoly theory seems to ignore what is actually going on.

Consider pricing and entry behavior. One of the things that is supposed to differentiate oligopolistic markets from competitive markets is that firms are price-makers rather than price-takers. A number of case studies and some more general empirical work has suggested that many firms use relatively simple rules of thumb for setting prices—markup rules, target normal rates of return, etc. (see Scherer, p. 173, and A. Kaplan, Dirlam and R. Lanzillotti). These pricing rules appear to be important determinants of short-run pricing behavior in oligopolistic markets during periods of rapid changes in demand, technology, and input prices. There is a need to understand the price adjustment process better and to make use of models of price formation to predict pricing behavior in oligopoly markets. What is the nature of these rules of thumb? Why might they be different for different products, different market structures, and industries of different vantages (M. Piore)? How important are internal signals such as inventories and input price changes relative to external signals like the prices and market shares of rival firms (especially in markets with differentiated products)? Do firms even think about *potential* entrants or do the realities of bounded rationality make the processing of internal information and the monitoring of a few rivals all that is really possible? It is apparent that pricing rules of thumb and more complicated price decision-making processes are in fact the reality in which most firms operate.

Entry both real and potential plays an important role in virtually all approaches to the theory of the firm and the theory of markets whether conventional or unconventional (S. Winter). How firms in oligopolistic markets take potential entry into consideration when setting prices or building capacity will have important implications for both short-run and long-run behavior and performance. Given the important role of entry in many of the formal models, as well as in the oral tradition of industrial organization, it is very surprising that there have been such limited efforts directed at building a richer understanding of who this character, the "potential entrant," might be, what the nature of the entry decision process is, the nature of the interdependence *between* potential entrants (R. Sherman and T. Willet), and how existing firms perceive potential entry and react to it.

Instead of assuming that some simple type of interrelationship exists among firms, more effort might be directed at both theoretical and empirical modeling of pricing and entry decision processes themselves, in different kinds of markets including the implications of organizational structure, the nature of the product and technology, the history of the industry, and other important institutional characteristics. The effort may not only imply new mathematical and analytical approaches, but also require one to leave the office and library to spend some time with actual firms that make actual pricing decisions.

Can one indeed pursue a program such as this and come up with more than just a catalogue of descriptions? I believe that it can indeed be done, but it requires an analysis of the ways in which decision-making processes evolve in response to various phenomena which characterize the real world environment in which firms operate. Contact with actual firm decision-making processes can be helpful in suggesting the kinds of phenomena which influence the decision-making structure and the nature of alternative processes. More formal analysis and empirical work can seek to provide simple structural models of these internal processes and analyze the ways in which individual firm behavior adds up to observed market behavior in both the short run and the long run.

A number of important phenomena appear to have implications with regard to pricing and entry decisions as well as other important decision-making processes. Let me suggest what these phenomena are and discuss each briefly.

A. Uncertainty

Firms operate in a dynamic world characterized by a great deal of uncertainty. For example, a firm will normally expect to have some random variation in demand from one period to the next. At a particular output and price level its inventory policy serves as a buffer between transitory fluctuations in orders and its production schedule. However, one is always uncertain whether a particular change in orders represents a random fluctuation or a secular shift in demand. If it is the latter, both short-run and long-run changes in prices and production plans may be called for. There is some evidence that firms have fairly simple inventory rules which trigger adaptive behavior by the organization. However, the type of behavior that is observed appears to differ from one industry to another. In some industries the immediate response triggered by a perception of a permanent fall in demand is a price reduction (R. Cyert and J. March, 1963). In other industries the response may be a decrease in production (or ordering for a retail firm) but the maintenance of existing prices (automobiles). The nature of such differential responses no doubt depends on characteristics of the product and technology as well as inventory holding costs, but is also heavily influenced by considerations of bounded rationality, contracting (and recontracting) costs, organizational structure of the firm, and market ethos. As a result we can expect to observe differences in response to changes in demand, input prices, taxes, etc. from one industry to the next *given* a particular level of a traditional market structure index such as the concentration ratio.

B. Bounded Rationality

It has long been recognized by psychologists and some economists that human beings are not capable of nor inclined toward continuous global optimization given all readily available information (H. Simon). Rather, decision makers opt for relatively simple rules of thumb to guide decisions. In addition, the status quo has certain stability characteristics arising from satisficing rather than maximizing behavior. Since it is expected that oligopolistic markets will be relatively more insulated from competitive pressures than are perfectly competitive markets, one might expect the existence of rule of thumb decision making and the sluggish response to change arising from satisficing behavior to be even more prevalent in such markets.

In addition, given a market ethos characterized by cooperation rather than by hard-nosed rivalry, simple rules of thumb may be desirable as a means of coordinating such cooperation.

Recent research by R. Radner has shown that considerations of bounded rationality can in fact be cast in a rigorous analytical framework yielding interesting behavioral propositions. Radner's "firefighting" manager may be relatively impervious to changes in particular economic circumstances if the effects are not large enough to reach the top of the manager's list. Among other things, firms exhibiting this kind of managerial behavior may not respond quickly to changes in certain costs or to the entry of new rivals if larger "fires" exist which will be fought first. If such behavior exists, it may have important implications for the effectiveness of alternative public policy instruments—for example, the use of Pigouvian pollution taxes vs. the use of mandatory rules and controls. To the extent that such rule of thumb behavior is more prevalent in insulated oligopoly markets, it might help to explain relative price rigidities and give us a deeper understanding of the importance of entry, as well as to indicate the desirability of applying different public policy instruments to sectors with different market structures.

C. *Information and Contracting Costs*

The existence of information and contracting costs have important implications for many aspects of firm behavior. The oligopoly firm is not only concerned about information regarding the prevailing market price, input costs, etc., but is also concerned about what rival firms are doing and what potential entrants might do. The firm's ability to monitor and respond to the actions of rivals, both real and potential, is limited by considerations of both bounded rationality and information costs. Its ability to form, monitor, and enforce informal collusive agreements is determined by the same considerations. The smaller are information and contracting costs, the greater will be the ability of a small group of firms to behave the way one single monopoly firm behaves. The larger are information costs, the less likely will a firm be able to identify and react to the threat of potential entrants. Similarly, the more costly is information about actual prices, costs, and profits achieved by existing firms, the smaller the set of potential entrants and the less likely will be actual entry from this set of firms, other things equal.

The notion of "proximity" is important, especially with regard to information about prices, entry, and technology. While by proximity I mean the closeness of a particular firm to others, I do not conceive of it in a geographical sense. A firm may be close to another firm because they produce the same product, use similar technologies, or are in contact with one another via market exchanges of products. A firm may be closer to another firm to which it sells and/or buys products than it is to a firm in its own market, especially with regard to actual transactions prices. Firms with similar technologies may be closer to one another than firms which produce complementary products. Firms borrowing money from the same financial institutions may be close to one another even though they produce different products and use different technologies. The topology of the terrain on which the firm operates is determined by much more than a product dimension. It is determined also by a technology and transactions dimension. To the extent that a firm has search processes regarding products, prices, costs, profits, and technologies, it will look most intensely at those firms which are near it because information costs are low. The more densely packed is the space surrounding the firm (across all dimensions), the lower are the information costs per bit of information, but the more the information that must be collected, the higher the contracting and enforcement costs if coordination of behavior is desired. Oligopolistic coordination would be difficult in such a market. Alternatively, the firm might have only a small number of existing firms producing the same product which are in close proximity. Information costs per bit of information from these firms would be low, as would total information costs and contracting costs. It would be costly to obtain information about other firms not in the product market, but these other firms would face the same problems. This situation facilitates the persistence of simple decision-making rules and monopolistic coordination.

Considerations of information and contracting costs have not been used extensively in the analysis of firm and market behavior. Nelson and Winter include both rules of thumb and the notion of proximity in an evolutionary model of economic growth and technological change. Their simulation approach facilitates an analysis of the adding up characteristics of a market composed of firms with particular behavioral rules. O. Williamson has applied the idea of contracting costs as part of his institutional failures approach to internal organization. In a simple satisficing model of pricing decisions of regulated firms, I have tried to specify how information about the unobservable allowed rate of return is obtained from observations of other firms. An extension of these approaches to deal explicitly with the oligopoly problems would be fruitful.

D. *Organizational Structure*

A firm's organizational structure is itself partially determined by considerations of uncertainty, bounded rationality, transactions costs, and technology. The complete characterization of the internal organization of the firm should include not only measures of hierarchical complexity, but also information gathering and processing mechanisms and decision-making structures. But since many large firms produce several products and decision-making processes evolve over time, once the basic organization is formed it is worthwhile to examine regularities that link stimulus with response via particular organizational structures. Attempts to relate characteristics of the organizational structure to decision making in the oligopoly situation have been quite limited (Cyert and March, 1955 and 1956), but are nevertheless of great interest. This is especially true with regard to antitrust policy, since it can influence organizational structure in certain circumstances. Organizations with complex hierarchies and centralized decision making are likely to respond more slowly and more routinely to changes in costs, demand, and actions of rivals and potential entrants than would a less hierarchical and more decentralized decision-making structure. But the centralized decision-making unit may be better able to integrate different kinds of information about the firm's activities and environment and to pursue carefully coordinated policies regarding pricing, production, advertising, etc. To the extent that some decisions (for example, pricing) are made at a different level of the hierarchy than are others (let's say production decisions), we may observe what appear to be biases in the responses to changes in the economic environment (like price rigidity but output flexibility). It would be interesting to see how much of the relative price rigidity often associated with concentration is really determined by differences in organizational structure. To the extent that organizational structure influences the nature and speed of a firm's responses, further analysis along these lines may also be useful in designing effective antitrust remedies.

E. Market Ethos

Perhaps the most difficult thing to get a handle on is what I call the ethos of the market. Some industries are characterized by social and historical relationships which favor cooperative behavior rather than hard-nosed rivalry. Behavior which has been characterized by "conscious parallelism" or "tacit coordination" is obviously facilitated in a market in which firms both want to coordinate and trust one another. I suspect that such a cooperative ethos is most prevalent in fairly old industries which are growing fairly slowly and where firms are close to one another in the sense used above. Rapidly expanding industries selling new products and declining industries are less likely to exhibit the cooperative ethos. Entry of new capital as well as new owners (via merger or takeover) will also affect the ethos of the market. Market ethos and internal organizational ethos (A. Hirschman) are certainly closely related. It is tempting to dismiss this phenomenon as being outside the domain of economics and hand it to sociologists and psychologists. I do so only reluctantly, because I have the feeling that market ethos is an important determinant of market behavior in small numbers situations. To the extent that other social scientists do have something worthwhile to say about this phenomenon, I hope that we will make use of it in our policy analysis and policy prescriptions for particular markets and not simply ignore it.

IV. Conclusion

Pricing and entry behavior are only two of several areas where a deeper understanding of decision-making processes and how they evolve in different market contexts is extremely important. Research and development and finance are prime candidates. Space doesn't really permit me to go into them, however, and the first has been discussed quite nicely elsewhere (Nelson 1972). But since I've trampled over many of the flowers in the garden, let me step on a few more in conclusion.

The sick sister of the structure-conduct-performance nexus of industrial organization is the conduct part or, as I would rather refer to it, behavior. The oral tradition of industrial organization abounds with many behavioral stories about pricing, entry, research and development, financing, etc., but they have not been incorporated into our theoretical conception of industrial markets. We have spent too much time calculating too many kinds of concentration ratios and running too many regressions of these against profit figures of questionable validity. We have spent too little time analyzing regularities in behavior that arise from structural characteristics other than concentration, including the structure of internal organization, the nature of basic learning, diffusion, and information processes, the closeness of products and technologies, the role of financial institutions, and yes indeed, considerations of business psychology and sociology. We haven't done it because the traditional tools of the theory of the firm are not very helpful. Nevertheless, the essence of the oligopoly problem is behavior, and if the tools are not to be found in the conventional theory of the firm, we might consider developing tools that are appropriate. Hopefully, the industrial organization area will in this way play an important leadership role in the extension and revision of the conventional theory of the firm rather than be its prisoner.

Oligopoly Theory, Communication, and Information

By MARTIN SHUBIK*

The stage is set for the development of a mathematical institutional economics which is simultaneously more abstract and more institutional than much of economic theory to date. The need for this development can be seen clearly by examining both the successes and failures of oligopoly theory.

Oligopoly theory has been the skeleton in every economic theorist's closet. Virtually every course in theory has a few hours spent in telling the students about the problems posed and showing them a few classical "solutions," after which the subject is dropped. The reason for this treatment is because we do not have a generally accepted adequate theory of oligopoly.

The reasons why we do not have a satisfactory theory are central to many economic problems. They exist for microeconomic models of competitive markets and they are hidden in the assumptions made in macroeconomic models. However, it is possible to gloss over the basic difficulties in these because, although they are still there, they do not appear to play as central a role as they do in oligopoly theory.

The key items are:

(1) the number and "size" of economic agents,
(2) the communication system,
(3) the state of information,
(4) the specifics of structure of both industrial and financial institutions, and
(5) the roles and goals of economic actors.

These items primarily involve the description of the structure of a firm, industry, or market. Considerations of structure (especially in reference to information and communication) cannot easily be separated from considerations of behavior. Thus we may need to reconsider the nature of the decision making of the individual we choose to regard as the economic decision maker.

I. Different Approaches to Oligopoly Theory

There are four broad approaches to oligopoly theory which merit distinguishing. Not only are they complementary with each other, it is my belief that in the new theory that is emerging they will come together. The approaches are:

(1) mathematical models of oligopolistic competition,
(2) institutional studies and industrial organization,
(3) "neoclassical" oligopoly theory, and
(4) behavioral models of oligopoly, the "new industrial organization" and gaming experimentation.

Ever since Cournot, oligopoly theory has provided a rich source of models for the mathematically inclined. The works of A. A. Cournot, J. Bertrand, F. Y. Edgeworth, H. Hotelling, T. Bowley and others attest to this as do the more recent works using game theory including R. J. Aumann, R. Selten, Shubik, B. Shitovitz, L. Telser, and others.

Most of the mathematical models have

---

been static. They have divided more or less naturally into those stressing some variant of a noncooperative equilibrium as a solution and those considering cooperative solutions such as a contract curve or the core.

The research and teaching on industrial organization has scarcely intersected with the mathematical work, although this is now beginning to change. Nevertheless, until recently the painstaking detailed studies of individual industries and firms, such as those of A. F. Kahn and M. G. DeChazeau, J. Peck, F. M. Scherer, J. B. Dirlam, and others, have been rarely if ever read by those concerned with mathematical models. Being institutionally oriented, this work may be read by lawyers before other economists. (See, for example, H. Packer.)

Neoclassical oligopoly theory is scarcely well defined, but I would lump under this title E. H. Chamberlin, W. Fellner, H. Brems, F. Machlup, G. Stigler, H. von Stackelberg, P. Sylos-Labini, J. J. Bain, and several others. They are all less mathematical than the first group and less institutional than the second. Chamberlin's contribution, for example, was mathematically less rigorous than that of Cournot, but contained much more relevant economic modeling. Bain's contribution on the study of entry is closer to an institutional study than the others in this group.

The key characterizing features of what I have called "neoclassical oligopoly theory" are that the analysis is in an open or partial equilibrium context; much of the discussion is cast in dynamic or quasi-dynamic terms; information implicitly plays a role; money explicitly plays a role (trade is in goods for money and vice versa) and the solution sought is some sort of noncooperative or quasi-cooperative equilibrium.

In general, in this type of theorizing (with some exceptions, Bain and Brems, for instance) there is little in the way of micro detail on the differences in the communication and information patterns in different industries or on critical technological factors which limit the scope and timing of moves.

This type of oligopoly theorizing is sufficiently spiritually close to the style of Marshall's partial equilibrium analysis and comparative statics that it supplies the major source for the two or three lectures on oligopoly that are thrown into the microeconomics courses.

The fourth approach to oligopoly theory has come about through a basic dissatisfaction with the other three. The key characterizing feature of this approach is a central concern with the explicit description of process. It is explicitly concerned with dynamics and with disequilibrium. There are possibly three different modes of development which can be discerned. They are:

(1) behavioral models of the firm and simulations,
(2) experimental oligopoly investigations, and
(3) mathematical models of search and other economic activity under incomplete information.

These approaches cannot be easily compartmentalized as they overlap. The first is best characterized by the work of R. M. Cyert and J. G. March, R. Nelson, S. Winters, and several others. It is spiritually linked to the large business games, such as the Carnegie Tech game, as well as to operations research work in marketing, production scheduling, finance, and other special functions.

An important link among economic theory, operations research, and computer simulation of behavior comes in the attempts which have been made to build models of the behavior of specific firms or parts of firms (see A. M. Schrieber). Much of this work is done without academic blessing; many studies done by and for private firms do not see the light of academic day and probably many do not deserve to be taken too seriously. Nevertheless, the efforts expended in attempting to construct detailed simulations are beginning to provide a connection between institutional and theoretical studies. The simulations are frequently rich in detail, yet at the same time spell out process.

Experimental oligopoly research is small relative to other scholarly activities, but since 1948 it has been growing and includes work by Chamberlin, T. Dolbear, L. Fouraker, J. Friedman, A. Hoggatt, Selten, Shubik, S. Siegel, V. Smith, and others.[1] There are several messages that this work has to deliver, the major one being that the specific details of communication, information, and the mechanisms of the market have considerable influence on the play when numbers are few.

Most of the experiments have employed students or individuals who are not senior businessmen; the time of play has been relatively brief and the stakes have been for the most part small or nonexistent. Thus what we are learning about is the behavior of students playing in business or economics games with low financial incentives and little if any institutional identification. Even so several useful observations can be made. Numbers play an important role. Without face-to-face communication the numbers in an experimental game appear to be 1, 2, 3–6, and "many." Information overload and computational limitations are also clear in the behavior of business game players. The coding and information processing step going from a matrix game to one with balance sheets is large. In all of the work the importance of sociopsychological variables is evident. These include "bargaining ability" in the work of Siegel and Fouraker, "trust" and "cooperativeness" in the work of Hoggart, T. C. Liu, and others. Furthermore, different approaches to cooperation and to decision making are evident in the work of Siegel and Fouraker, D. Stern, Shubik and G. Wolf, and others.

The third of the new approaches covers explicit models of search and behavior where information is scarce and costly. This includes work by P. Diamond, H. Leland, J. McCall, D. McFadden, M. Sobel, M. Spence, and others.[2]

II. A Reconciliation of General Equilibrium and Oligopoly Disequilibrium

General equilibrium theory and partial equilibrium offer us the concept of the efficient anonymous market price system. Oligopoly theories, in contrast, suggest the noncooperative equilibrium: quasi-cooperative solutions involving leaders and followers, "kinked oligopoly reaction functions," cooperative agreements, or a variety of behavioral mechanisms.

When general equilibrium theory is contrasted with work in oligopoly theory, it appears to be so pristine, general, mathematical, and noninstitutional that it makes the latter appear in utter disarray. This could be because oligopoly theorizing is not abstract enough or because there may be within the presentation of the general equilibrium system a false generality which conceals many gaps in basic modeling. I believe the latter is true.

There are at least eight desiderata for any robust economic model of markets which any student of oligopoly will recognize. A reasonable model should:

(a) depend explicitly on the number of participants;
(b) contain an explicit description of the functioning of the market mechanism;
(c) be able to handle nonsymmetric in-

---

[1] For a detailed bibliography, see M. Shubik.

[2] A recent article by M. Rothschild provides a survey.

formation conditions;

(d) be defined for all positions of disequilibrium as well as equilibrium;

(e) be able to handle markets with few traders and other markets with many traders together;

(f) have assets and capital structure play an important role;

(g) have money and finance play an important role; and

(h) be consistent with behavioral models of economic process.

The general equilibrium model as presented by K. J. Arrow, Gerard Debreu, and others fails to satisfy any of these criteria. The noncooperative behavioral model first suggested by Cournot as a solution to oligopolistic competition can be modified so that it satisfies all eight.[3] The work of Chamberlin, Stackelberg, Fellner, and many others and the recent work in game theory as applied to economics can be interpreted as variations on this theme.

The variety and difficulties manifested in oligopoly theory are a reflection of the maze of institutions and complex of processes which make up economic life. There is an underlying structure to these economic processes but in order to appreciate it we must be simultaneously more abstract and more concrete or institutional than most of current microeconomic theory. The theory of games, the new work on search and decision making under uncertainty are beginning to provide the basis for the former; process models, simulations, and direct empirical work are providing the latter.

EMERGING STRUCTURAL CHANGES IN TRANSPORT AND PUBLIC UTILITIES

Northeast Railroads: Restructured or Nationalized?

By ALEXANDER LYALL MORTON*

The intractability of the current Northeast rail problem owes to the fact that the demands of shippers, the demands of rail employees, the claims of creditors, and the demands of public transport policy cannot all be met by the Northeast rail system—they add up to more than the rail system, operating in the competitive environment it does, can produce. Even if the claims of the creditors on the bankrupt estates were to be extinguished, the present demands of the other three claimants could not be met by a self-supporting rail system. Briefly stated, the situation is thus: various labor practices on the railroads (by no means the fault solely of rail labor unions) raise rail costs to the point that most freight traffic (and virtually all passenger traffic) has been lost to other modes of transport and to the point that railways are only marginal competitors for most remaining freight traffic. Large rail shippers use their muscle, playing railroads off one against another and against competing modes to hold down rail freight rates and to extract services from the carriers at prices below cost. Government policy imposes a host of common carrier obligations on the railroads, requiring "essential public services" to be performed and cross-subsidized by profits on other services. Intense competition from other modes and the power of large shippers have eroded such profits (which once derived from markets in which railroads enjoyed monopoly powers). The owners of the Northeast railroads have for some decades been the victim of this squeeze play, but now their resources have been largely exhausted, and the Northeast rail plant is in shambles. To whom do employees, shippers, and the beneficiaries of public policies turn next to fill the gap created by their excessive demands upon the rail system?

The political process has intervened in the search for a solution. Declaring the bankrupt railroads to be of concern to the national interest, Congress passed the Regional Rail Reorganization Act of 1973, thereby removing the solution from the exclusive jurisdiction of the bankruptcy courts. In fact, the political process did not have to intervene; conventional thinking has for many years exaggerated the importance of the railroads to the Northeast economy (as we will suggest below). There is, of course, a risk to the government's taking on this responsibility: Will the political process be able to force compromise and sacrifice upon the competing interest groups, or will it ultimately resort to the public purse to squeeze past the crisis?

The proper remedy is to force the claimants to moderate their demands so as to create a viable, self-supporting rail system, for there is no good reason why freight transport should be a subsidized factor of production. Happily, the medicine need not be too bitter, but it does require some rather radical departure from past practice.

---

* Harvard Business School.

First, let us look at the changes labor must accept. Restrictive labor practices raise the labor cost of rail freight transportation to roughly equal the labor input of private and exempt motor carriage, thereby contributing to the loss of rail traffic to trucks. Work rules, craft lines, seniority agreements, and a host of related restrictions severely limit and constrain the specific tasks that may be assigned to any individual rail employee. The purpose of these rules is to share the "available work" more widely, thereby protecting jobs and income. But these understandable goals of labor can be served in a much better way. Slow, unreliable train service and the rundown condition of track and equipment reveal that there are plenty of opportunities for using extra useful service from every present employee to improve service and upgrade plant. To guarantee that greater labor productivity is not turned against labor, employment and income guarantees should be issued. In fact, improved rail service would generate rail freight traffic, actually improving employment prospects in the future. Greatly improved rail labor productivity is one essential remedy for the Northeast rail problem.

Let us turn now to the reform required of shippers and public transport policy. Shippers, local communities, and passengers exploit the common carrier obligations and regulation of the railroads to obtain and preserve rail services at prices below their true cost. The bankruptcies of Northeast railroads were caused to a large degree by forcing the carriers to provide many services at unremunerative rates, and the restoration of these carriers to profitable operation requires an end to this practice.

The proper way to do this is to release railroads from common carrier obligations altogether. Free railroads to negotiate detailed service contracts with individual shippers that specify what services will be provided and what price will be charged, and let the railroads abandon all services whose cost the market refuses to bear, just as most other private industry is permitted to do.

To understand why such a radical cure is necessary and, at the same time, feasible or safe, one must look at the intense competition Northeast railroads now face. American industry has a variety of transport modes to choose among to move its freight; the railroads receive only about one out of every eight dollars spent on intercity freight movement. Equally important, industry has a rich variety of alternatives to the purchase of transportation; among the most important of these are decentralization of production and substitution of locally available materials for those which must be moved longer distances. Thus rails are but one alternative in an array of logistical options that industry has. Let us focus more intently on the truck as a competitor of and alternative to rail. The cost functions of rail and private and exempt truck operations are today nearly identical. This is perhaps astonishing because of the apparent broad differences between the two technologies, but it is nonetheless true. Any commodity can move by truck and move at a cost that is, at best, only slightly higher than the current cost (to the railroad) of rail movement. Trucks can and do carry large amounts of virtually every commodity there is to be moved. (Coal is the commodity whose movement railroads most dominate; yet trucks move about one-sixth as much coal as rail and their share is growing.) Virtually every shipper and every community has unhindered access to trucking for its freight needs. Modern highways serve virtually every location; there is no legal restriction on entry into private trucking; and the near total absence of economies of scale associated with truckload operations means that even the comparatively small shipper whose freight needs will fully utilize only a truck or two has access to virtually all the benefits of truck transport. Because of its broad availability, cost competitiveness with rail, and generally better service and greater convenience, trucking has grown to be the dominant mode. Trucks presently receive five times the revenues of railroads for intercity freight movements.

Trucks, then, can and do compete on a cost basis for virtually every type of traffic the railroads carry, and the cost of private and exempt trucking places a very firm and reasonable ceiling on the price an unregulated railroad industry could possibly demand for its service. The one area where railroads can, one may argue, develop distinct cost advantages over trucks is in high-volume, long-distance movements of bulk commodities such as coal, ore, petroleum products, chemicals, construction aggregates, lumber, and grain. Industries that rely on these raw materials have come increasingly to locate along the expanding network of navigable waterways, however, and water carriers, either alone or in conjunction with truck, now offer cost-competitive and surprisingly widespread competition to the railroads for that one type of traffic that may be somewhat insulated from truck competition. Also, production and distribution of these bulk commodities have become highly concentrated in the hands of a few, very large firms. The size and market power of these firms more than protect them from abusive treatment by railroads.

Shippers no longer require common carrier obligations and regulation to protect them from the railroads. Rather, freedom from these obligations may even be necessary to the survival of railroads in the Northeast. Competing modes are closing in on rail freight transport. They have already diverted vast amounts of rail traffic in the Northeast and they are becoming ever more cost and service competitive for the rest. The point is being approached where the volume of rail traffic remaining in the Northeast fails to achieve the economies of scale and density necessary to support the Northeast rail system in anywhere near the form we know. The grip of the Northeast railroads on the freight market is so tenuous and uncertain that, far from being restrained, they must be given the freedom and encouraged to compete aggressively for all the traffic they can get.

Given this freedom, the railroads may once again carve out for themselves a defensible position in the Northeast. The opportunity is there. The dedicated, or unit, train—a train composed of cars designed specially for their load that shuttles back and forth between specified origin(s) and destination(s)—permits substantial savings in labor, fuel, and capital costs over conventional train operations. It should be used more widely for the movement of bulk commodities and those manufactures that generate repetitive, high-volume movements. Piggybacking—the movement of truck trailers on railway flatcars—enables the railroads to recapture other traffic that has been lost to trucks. The railroad's cost advantage over trucking lies primarily in line-haul efficiency. Piggybacking permits railroads to capture the line-haul portion of intercity freight movements while leaving to trucks the local pickup and delivery functions that trucks clearly do best. Northeast railroads have been moving toward greater use of unit trains and piggybacking, but the common carrier obligations imposed on railroads severely retard what should amount to a technological revolution, a massive restructuring of the industry.

Having intervened in the Northeast rail problem, is the political process facing up to the hard decisions outlined above? The signs are not encouraging. The Regional Rail Reorganization Act itself virtually foreclosed the possibility of substantial reform of restrictive labor practices. The one lever the authors of the Act possessed to goad management and labor into work-rule revision was the offer of protection for any employees that might be affected in rationalizing the Northeast rail system. The Act, however, grants this protection, on extraordinarily generous terms, without requiring any meaningful change of labor practices.
